# Estimation of Sockeye Salmon Escapement in Mortensens Creek, Izembek National Wildlife Refuge, 2006; and 2001 to 2006 Run Comparisons 

## Alaska Fisheries Data Series Number 2007-7

Anchorage Fish and Wildlife Field Office Anchorage, Alaska
May 2007

The Alaska Region Fisheries Program of the U.S. Fish and Wildlife Service conducts fisheries monitoring and population assessment studies throughout many areas of Alaska. Dedicated professional staff located in Anchorage, Juneau, Fairbanks, and Kenai Fish and Wildlife Offices and the Anchorage Conservation Genetics Laboratory serve as the core of the Program's fisheries management study efforts. Administrative and technical support is provided by staff in the Anchorage Regional Office. Our program works closely with the Alaska Department of Fish and Game and other partners to conserve and restore Alaska's fish populations and aquatic habitats. Additional information about the Fisheries Program and work conducted by our field offices can be obtained at:

## http://alaska.fws.gov/fisheries/index.htm

The Alaska Region Fisheries Program reports its study findings through two regional publication series. The Alaska Fisheries Data Series was established to provide timely dissemination of data to local managers and for inclusion in agency databases. The Alaska Fisheries Technical Reports publishes scientific findings from single and multi-year studies that have undergone more extensive peer review and statistical testing. Additionally, some study results are published in a variety of professional fisheries journals.

# Estimation of Sockeye Salmon Escapement in Mortensens Creek, Izembek National Wildlife Refuge, 2006; and 2001 to 2006 Run Comparisons 

Jeffry L. Anderson and Cheryl A. Dion

#### Abstract

A fixed picket weir and underwater video monitoring station was operated on Mortensens Creek from 18 June to 16 September 2006. Sockeye salmon Oncorhynchus nerka were the most abundant species counted through the weir ( $N$ $=14,788$ ) followed by coho salmon $O$. kisutch $(N=5,003)$ and Dolly Varden Salvelinus malma ( $N=890$ ). Most sockeye salmon passed the weir at night during the high tide cycle. The weir was removed prior to the peak coho salmon run in 2006 because of budget constraints; therefore, our estimate is a minimum number. Sockeye salmon sampled at the weir were predominantly male (53\%) and age 1.3 fish comprised $67 \%$ of the run. Female sockeye salmon sampled at the weir ranged in length from 504 to 581 mm and males ranged from 526 to 626 mm . Age, sex, and length data were not collected from coho salmon in 2006 because we were unable to sample the entire run. In 2006 we compared counts from motion-triggered video files to counts made by reviewing continuously recorded video files; counts were nearly identical. Motion detection functioned well except for times of high fish passage (> 300 fish/h) when small breaks in recording made it difficult to accurately count fish; continuously recorded video files were used to enumerate escapement during times of high fish passage. From 2001 to 2006, sockeye salmon escapement at the Mortensens Creek weir ranged from 4,268 to 21,703 (mean $=11,664$ ) and coho salmon escapement ranged from 3,836 to 8,184 (mean $=5,478$ ). The sex ratio of sockeye salmon varied over the years of the project, but no trends were apparent; age composition for sockeye salmon was similar over all years with age 1.3 predominant. Mean lengths of sockeye salmon were similar over all years of the project. Coho salmon sex composition also varied over project years without any apparent trends and age 2.1 fish were predominant each year. Mean lengths of coho salmon appeared to decline in 2004 and 2005, but we did not measure length in 2006 and did not determine if this trend continued. Sockeye and coho salmon populations in Mortensens Creek can continue to support harvest by all user groups at current levels, although the commercial fishery has the potential to overharvest this small sockeye salmon run.

## Introduction

Subsistence harvest of salmon is important to residents of the villages of Cold Bay and King Cove, and residents of the two villages harvest about 4,700 sockeye Oncorhynchus nerka and 3,000 coho O. kisutch salmon each year (2000 to 2004 averages; Tschersich 2006). The outlet of Mortensens Creek is one of the few areas where sockeye and coho salmon are available for harvest by subsistence users from King Cove and Cold Bay. In 1999, escapement of sockeye salmon in Mortensens Creek was estimated to be 3,600 fish and an estimated 1,378 sockeye salmon were harvested in the subsistence and commercial fisheries (Shaul and Dinnocenzo

[^0]2000). About $30 \%$ of the subsistence harvest of sockeye salmon was taken by Alaska residents living outside of Cold Bay and King Cove. Also in 1999, 279 coho salmon were harvested in the commercial and subsistence fisheries (Shaul and Dinnocenzo 2000). Management of both species was based on aerial surveys of escapements, but effectiveness of these surveys was limited by dark stream bottoms, turbid water, and inclement weather. An escapement goal for Mortensens Creek of 3,200 to 6,400 has been established for sockeye salmon, but currently there is no goal for coho salmon (Nelson and Lloyd 2001).

The Alaska Department of Fish and Game (ADFG) was concerned that the lack of an in-season estimate of sockeye and coho salmon escapement into Mortensens Creek could jeopardize the continued health of these runs, as well as limit opportunities for subsistence and sport fishing (Arnold Shaul, ADFG, personal communication). Additionally, King Cove residents were concerned about sport fishing effects on coho salmon. Although specific sport harvest data are not available for Mortensens Creek, the ADFG estimated an average sport harvest of 671 coho salmon from 1996 to 1998 in the Cold Bay area, which includes Russell and Mortensens creeks (Howe et al. 1997, Howe et. al. 1998, and Howe et al. 1999).

In 2001, the King Salmon Fish and Wildlife Field Office (KSFO) received funding from the U.S. Fish and Wildlife Service (USFWS) Office of Subsistence Management to address these concerns. Beginning in January 2007, the KSFO has become the Fisheries Branch of the Anchorage Fish and Wildlife Field Office. The KSFO operated a fish counting weir on Mortensens Creek to estimate escapement of sockeye and coho salmon. Project objectives were to:

1. Enumerate daily passage of sockeye and coho salmon through a weir on Mortensens Creek;
2. Describe the run-timing of sockeye and coho salmon through the weir;
3. Estimate the sex and age compositions of sockeye and coho salmon such that simultaneous $90 \%$ confidence intervals have a maximum width of 0.20 ;
4. Estimate the mean length of sockeye and coho salmon by sex and age;
5. Determine if the sockeye and coho salmon returns to Mortensens Creek are adequate to allow subsistence fishing; and
6. Determine if the sockeye and coho salmon returns to Mortensens Creek are adequate to allow sport fishing.

The USFWS is responsible for management of subsistence fisheries occurring in Mortensens Creek and prior to 2006 was also responsible for management of subsistence fisheries in Mortensens Lagoon. The ADFG manages commercial and sport fisheries in Mortensens Creek and Lagoon, and beginning in 2006 is also responsible for managing subsistence fisheries in Mortensens Lagoon. Subsistence fishing in Mortensens Creek and Lagoon requires a permit issued by the ADFG, and current regulations limit subsistence harvest in Mortensens Lagoon to 50 salmon per permit (5 AAC 01.423).

This report provides results from the 2006 field season, and also provides an overall project summary and run comparisons for sockeye and coho salmon, 2001 to 2006. Detailed information on previous years can be found in the individual annual reports (Whitton 2002 and 2003; Cornum et al. 2004; Dion 2005; Hildreth and Dion 2006).

## Study Area

Mortensens Creek is located on the southwestern tip of the Alaska Peninsula near the town of Cold Bay, Alaska, approximately 1,050 km southwest of Anchorage (Figure 1). Climate in the area is characterized by high winds, moderate temperatures, protracted cloud cover, and frequent precipitation (USFWS 1985). The drainage area of the Mortensens Creek watershed is approximately $18 \mathrm{~km}^{2}$, and consists of numerous springs and ponds, several small tributaries, and a shallow ( $<2 \mathrm{~m}$ ) 112-ha lake. Mortensens Creek is a low gradient tundra stream with stable stream banks, with a riparian area composed primarily of grasses and forbs. Turbidity in Mortensens Creek is relatively high, and can be aggravated by high winds which frequently churn up the substrate of the lake. Mortensens Creek discharges into Mortensens Lagoon, which feeds into the North Pacific Ocean via Cold Bay. Mortensens Lagoon is a shallow tidal area of approximately $2 \mathrm{~km}^{2}$, and is sheltered by two sand spits where it enters Cold Bay. Migrating salmon often stage in Mortensens Lagoon and enter Mortensens Creek when tide and wind conditions are optimal.

Mortensens Creek supports spawning populations of sockeye salmon, coho salmon, and Dolly Varden Salvelinus malma; chum O. keta and pink O. gorbuscha salmon are also present, but in limited numbers. Bering cisco Coregonus laurettae, sculpin Cottus spp., and starry flounder Platichthys stellatus have also been observed in Mortensens Creek, but abundance of these species is unknown.

## Methods

## Escapement Monitoring

The KSFO installed and operated a fish counting weir on Mortensens Creek from 18 June to 16 September 2006. We were unable to keep the weir in place for the duration of the coho salmon run (mid October) because the funding commitment for the project ended on 30 September and all project equipment needed to be removed from the field and returned to King Salmon prior to that date. The weir panels were constructed of 2-m long aluminum pickets with $2-\mathrm{cm}$ spacing between each picket. Each weir panel had a minimum of three cross pieces that were welded to the pickets to provide rigidity. Weir panels were supported by fence posts and an 8 -mm diameter galvanized aircraft cable stretched across the stream. The supporting cable was anchored to the stream banks using "dead men" buried vertically at a depth that allowed the cable to be suspended under tension just above the water surface. Weir panels were placed across the channel, connected together and to the supporting cable with plastic cable ties, and the continuous panel was tilted downstream in relation to stream flow to shunt debris to the water surface, thereby maintaining free-flow of water through the pickets. A permeable textile cloth was placed under the weir to prevent undercutting. A fyke was installed in the weir, leading to an upstream migrant live trap. The entire weir was inspected and cleaned daily and maintained as necessary to ensure integrity.

An underwater video monitoring system was incorporated into the weir to facilitate fish passage and reduce the number of fish handled. The system included an underwater camera, camera box, video monitoring chute, lights, and digital video recorders (DVR). Anderson et al. (2006) provides details of the video monitoring system design and components. The video monitoring system was operated $24 \mathrm{~h} / \mathrm{d}$ to allow unimpeded fish passage. Except for fish sampled in the live trap, all fish passage at the Mortensens Creek weir was enumerated with the video monitoring system in 2006.

Figure 1. Mortensens Creek weir location, southwest Alaska.

Two DVR were used in 2006 to test the effectiveness of the motion detection system. One DVR recorded full quality ( 30 frames/s) fish passage $24 \mathrm{~h} / \mathrm{d}$ and the date, time, and percent of remaining hard disk space were digitally encoded as a date time stamp on the video file. The second DVR was set to record full quality ( 30 frames/s) motion-triggered video files. Motion detection recording in the second DVR was activated in response to a moving object causing a change in the brightness in user-defined detection zones with user-defined trigger sensitivity. The second DVR was configured to record a 3-s pre-event in a memory buffer so the recorder could access and record the video that preceded each motion-triggered event. Motion-triggered video files were set to record for 10 s , but video footage would continue to record as long as fish were activating the motion detection. For a single fish passing directly through the video monitoring chute, 13 s of video were recorded (3-s pre-event plus a 10 -s motion-triggered event). The date, time, file number, and percent of remaining hard disk space were digitally encoded as a date-time stamp on each video file.

Effectiveness of motion detection was assessed by comparing hourly fish counts tallied from reviewing a constant recording of the selected hour of fish passage on the first DVR to counts tallied by reviewing motion-triggered video files recorded on the second DVR during the same hour. Count comparison hours were initially selected randomly each day, but were later selected randomly within the high tide cycle to increase the probability of selecting hours of high fish passage. Differences between motion detection and constant recording counts were investigated with scatter plots, a sign test (Zar 1996), and correlation analysis. Results were considered significant at $P<0.05$.

Fish counts were made by reviewing either motion-triggered video files or the constant recording of fish passage. When reviewing motion-triggered video files, we used the time/date search function of the DVR to retrieve the first file to review. The "Play" button was pressed and the recorded file would play back on the monitor. The DVR had numerous file review features that
assisted in identification and counting of passing fish. The image could be played forwards or backwards at various speeds, or paused and zoomed to assist in counting or species identification. Video files were reviewed sequentially until all fish passing through the video monitoring chute were identified and counted. Reviewing the constant recording of fish passage was similar to above, except only one continuous video file was reviewed.

Beginning in mid July when sockeye salmon started passing the weir in large numbers, fish counts were tallied every hour and the associated tide cycle (high or low) was recorded. These data were used to calculate hourly passage rates and to correlate fish passage with time of day and tide cycle. We also recorded wind speed and staff height throughout the course of the field season to investigate the effects of wind and tides on fish migration in Mortensens Creek.

Power to operate the video equipment was provided by a combination of two solar panel arrays, two wind generators, and a 12-V DC battery bank. A 3,000-W gasoline-powered generator and 75-A battery charger were also used as a backup power source when solar and wind energy did not meet our needs.

## Age, Sex, and Length Data

We collected sockeye salmon age, sex, and length (ASL) data using a temporally stratified sampling design (Cochran 1977) with statistical weeks defining strata. Samples were collected uniformly throughout the week (Sunday through Saturday). To avoid potential bias caused by the selection or capture of individual fish, all target species within the live trap were included in the sample even if the sample size goal for a species was exceeded. Although weir passage was stratified into statistical weeks a priori, strata for the analysis of sockeye salmon biological data at the Mortensens Creek weir were modified following the field season to represent actual weir passage (Table 1).

Samples for ASL data were collected using a dip net to remove fish from the live trap at least once daily or more often as the number of fish moving through the weir increased. Adult salmon were measured to the nearest mm (mid-eye to tail fork) and the sex of the fish was determined from secondary characteristics. One scale from each sockeye salmon was removed from the preferred area on the left side of the fish (Jearld 1983), cleaned, and mounted on gummed scale cards. Sockeye salmon scales were pressed and aged following the field season by ADFG personnel. Salmon ages are reported according to the European method described by Jearld (1983) and Mosher (1968), where the number of winters the fish spent in fresh water and in the ocean is separated by a decimal. Fish with scales that could not be aged were not included in the age analyses. Non-target fishes captured in the live trap were identified to species, enumerated, and released above the weir. Fish were not allowed to hold downstream of the weir. If this occurred, the live trap was closed and the video monitoring chute was opened to facilitate upstream passage.

Maximum weekly sample size goals for sockeye salmon were established such that simultaneous $90 \%$ interval estimates of age composition for each week have maximum widths of 0.20 based on a multinomial sampling model (Bromaghin 1993). The weekly sample size determined from Bromaghin (1993) was $n=121$ based on four age categories, and was increased to 142 to account for the expected number of unreadable scales (about $15 \%$ in past years). For some weeks, the sample size goal was expected to be a substantial fraction of the sockeye salmon passage. Therefore, during weeks of low passage when the maximum sample size goal could not

Table 1. Strata (time periods) used for analysis of sockeye salmon biological data at Mortensens Creek, 2006.

| Stratum | Dates |
| :---: | ---: |
| 1 | 18 Jun -15 Jul |
| 2 | $16-22 \mathrm{Jul}$ |
| 3 | $23-29 \mathrm{Jul}$ |
| 4 | $30 \mathrm{Jul}-5 \mathrm{Aug}$ |
| 5 | $6-12$ Aug |
| 6 | $13-19$ Aug |
| 7 | $20-26$ Aug |
| 8 | $27 \mathrm{Aug}-2 \mathrm{Sep}$ |
| 9 | $3-16 \mathrm{Sep}$ |

be practically obtained, about $20 \%$ of the weekly escapement was sampled. This was sufficient to describe the age composition and reduce the number of fish handled at the weir. For sample size determination, major age categories (1.2, 1.3, 2.2, and 2.3) were defined from previous work (Whitton 2002 and 2003; Cornum et al. 2004; Dion 2005).

Characteristics of sockeye salmon passing through the weir were estimated using standard stratified random sampling estimators (Cochran 1977). Within a given stratum $m$, the proportion of species $i$ passing the weir that are of sex $j$ and age $k\left(p_{i j k m}\right)$ was estimated as

$$
\hat{p}_{i j k m}=\frac{n_{i j k m}}{n_{i++m}}
$$

where $n_{i j k m}$ denotes the number of fish of species $i$, sex $j$, and age $k$ sampled during stratum $m$ and a subscript of "+" represents summation over all possible values of the corresponding variable, e.g., $n_{i++m}$ denotes the total number of fish of species $i$ sampled in stratum $m$. The variance of $\hat{p}_{i j k m}$ was estimated as

$$
\hat{v}\left(\hat{p}_{i j k m}\right)=\left(1-\frac{n_{i++m}}{N_{i++m}}\right) \frac{\hat{p}_{i j k m}\left(1-\hat{p}_{i j k m}\right)}{n_{i++m}-1},
$$

where $N_{i++m}$ denotes the total number of species $i$ fish passing the weir in stratum $m$. The estimated number of fish of species $i$, sex $j$, age $k$ passing the weir in stratum $m\left(\hat{N}_{i j k m}\right)$ was

$$
\hat{N}_{i j k m}=N_{i++m} \hat{p}_{i j k m},
$$

with estimated variance

$$
\hat{v}\left(\hat{N}_{i j k m}\right)=N_{i++m}^{2} \hat{v}\left(\hat{p}_{i j k m}\right)
$$

Estimates of proportions for the entire period of weir operation were computed as weighted sums of the stratum estimates, i.e.,

$$
\hat{p}_{i j k}=\sum_{m}\left(\frac{N_{i++m}}{N_{i+++}}\right) \hat{p}_{i j k m}
$$

and

$$
\hat{v}\left(\hat{p}_{i j k}\right)=\sum_{m}\left(\frac{N_{i++m}}{N_{i+++}}\right)^{2} \hat{v}\left(\hat{p}_{i j k m}\right) .
$$

The total number of fish in a species, sex, and age category passing the weir during the entire period of operation was estimated as

$$
\hat{N}_{i j k}=\sum_{m} \hat{N}_{i j k m},
$$

with estimated variance

$$
\hat{v}\left(\hat{N}_{i j k}\right)=\sum_{m} \hat{v}\left(\hat{N}_{i j k m}\right) .
$$

If the length of fish of species $i$, sex $j$, and age $k$ sampled in stratum $m$ is denoted $x_{i j k m}$, the sample mean length of fish of species $i$, sex $j$, and age $k$ within stratum $m$ was calculated as

$$
\bar{x}_{i j k m}=\frac{\sum x_{i j k m}}{n_{i j k m}},
$$

with corresponding sample variance $s_{i j k m}^{2}$

$$
s_{i j k m}^{2}=\left(1-\frac{n_{i j k m}}{\hat{N}_{i j k m}}\right) \frac{\sum\left(x_{i j k m}-\bar{x}_{i j k m}\right)^{2}}{n_{i j k m}-1} .
$$

The mean length of all fish of species $i$, sex $j$, and age $k\left(\hat{\bar{x}}_{i j k}\right)$ was estimated as a weighted sum of the stratum means, i.e.,

$$
\hat{\bar{X}}_{i j k}=\sum_{m}\left(\frac{\hat{N}_{i j k m}}{\hat{N}_{i j k}}\right) \bar{x}_{i j k m}
$$

An approximate estimator of the variance of $\hat{\bar{X}}_{i j k}$ was obtained using the delta method (Seber 1982),

$$
\left.\hat{v}\left(\hat{\bar{X}}_{i j k}\right)=\sum_{m}\left\{\hat{v}\left(\hat{N}_{i j k m}\right) \frac{x_{i j k m}}{\sum_{x} \hat{N}_{i j k x}}-\sum_{y} \frac{\hat{N}_{i j k y}}{\left(\sum_{x} \hat{N}_{i j k x}\right)^{2}} x_{i j k y}\right]^{2}+\left(\frac{\hat{N}_{i j k m}}{\sum_{x} \hat{N}_{i j k x}}\right)^{2} S_{i j k m}^{2}\right\}
$$

## Results

## Escapement Monitoring

An estimated 14,788 sockeye salmon migrated past the Mortensens Creek weir in 2006 (Table 2). Peak sockeye salmon passage occurred over a three day period from 8 to 10 August when over 6,600 fish passed the weir (Figure 2; Appendix A). In general, most sockeye salmon passed the Mortensens Creek weir at night during the high tide cycle (Figure 3). Sockeye salmon were first observed at the weir on 21 June and some were still passing the site on the last day the weir was operated ( 16 September). It is unlikely that many sockeye salmon entered Mortensens Creek prior to weir installation on 18 June or after the weir was removed on 17 September. Sockeye salmon passage rates at the Mortensens Creek weir averaged 17 fish/h over the course of the season (range 0 to 1,043 ).

An estimated 5,003 coho salmon, 138 pink salmon, 25 chum salmon, and 890 Dolly Varden passed the Mortensens Creek weir in 2006 (Figure 2; Appendix A). Coho salmon were first observed at the weir on 23 August, and a peak count of 2,092 fish occurred on 7 September. Although counts dropped considerably after this date, we do not know how much of the coho salmon run occurred after the weir was removed on 17 September. Starry flounder ( $n=108$ ), Bering cisco ( $n=4$ ), and sculpin (not counted) were also observed at the Mortensens Creek weir in 2006. Underwater video was used to count almost all fish passage at the Mortensens Creek weir in 2006. The only time fish did not pass through the video monitoring chute was when we needed to collect fish for biological samples in the live trap.

Thirty-seven hours were selected to compare paired counts from motion detection files and continuous recordings of fish passage in 2006 (Figure 4; Appendix B). Paired counts were identical for total numbers and individual species tallies for all but six of the selected hours. For five hours in which total counts differed, the maximum difference was only one fish. For the sixth hour in which total counts differed, a pink salmon was misidentified as a sockeye salmon during the continuous recording count, while the overall total fish count was the same for both methods. For the other five hours in which total counts differed: 1) a starry flounder was observed during review of the motion detection files, but was not observed during review of the continuous recording; 2) a sculpin was observed during continuous recording review that was bit recorded in the motion detection file; 3) one additional sockeye salmon was counted during the continuous recording review than was counted during the motion detection file review; 4) one additional sockeye salmon was counted during the motion detection file review than during the continuous recording review; and 5) one Dolly Varden was counted during the continuous recording review that was not recorded in the motion detection file until only its tail was visible and species identification was not possible. Counts from both methods were highly correlated ( $r$ $=0.99 ; P<0.001$ ) and a sign test did not detect a difference between the number of positive and

negative differences between data pairs $(Z=0.00 ; P=1.00)$. Fish passage rates for the selected hours averaged 19 fish/hr (range 0 to 116). For seven of the selected hours, no fish were observed with either method. Our random sampling of hours to compare did not include passage rates greater than 150 fish/h. However, we do not believe our sampling was biased because passage rates higher than 150 fish/h were only observed in $2 \%$ of all hours sampled and represented only $8 \%$ of all non-zero fish passage hours (Figure 5).

The crew used review of continuous recordings to enumerate and identify fish during high passage rates (> 300 fish/h) because motion detection was not adequate for accurate counts. During high fish passage rates ( $>300$ fish $/ \mathrm{h}$ ), motion detection files did not record constantly and 1 - to 2-s breaks in the recording made counting difficult as the crew was uncertain whether the tail of a fish seen exiting the field of view at the beginning of a file was the same fish that they had already counted entering the field of view from the previous file. Also, reviewing motion detection files during high passage rates did not provide any time savings benefits compared to time-lapse review since motion detection files essentially recorded constantly. Fish passage rates only exceeded 300 fish/h on ten occasions in 2006.

The use of motion detection files to enumerate passage was also affected by localized water conditions in 2006. Strong incoming tides combined with high winds caused extreme reductions in visibility on some occasions. The combination of strong tides and winds churned up mud in Mortensens Lagoon and caused visibility to be almost totally obscured for up to 5 min and to be

Figure 5. Histogram of non-zero passage rates of sockeye salmon at Mortensens Creek weir, 2006. Total non-zero hours counted were $n=25$ for video comparison counts and $n=308$ for all other counts.
noticeably poor for up to 15 min . Motion detection was not functional during these times, although review of continuous recordings was still possible. The crew was not able to adjust the motion detection sensitivity to trigger alarm recording when fish passed during these conditions.

Motion detection functionality was also affected later in the season by dirty glass in the camera box. Because of minor alterations to the video monitoring chute, necessary to correct intermittent fish passage problems, the crew was no longer able to clean the glass without completely disassembling the chute. Although the crew was able to adjust the motion detection sensitivity, fish would sometimes not trigger an alarm until they had almost completely passed through the field of view and review of motion detection files was not as efficient as when the glass was clean.

## Age, Sex, and Length Data

Age, sex, and length data were collected from 814 sockeye salmon from 27 June to 11 September. Eleven age classes were identified from scale samples in 2006, although only three age classes (1.2, 1.3, and 2.3) accounted for over $93 \%$ of the sample. Over all strata, age 1.3 fish comprised the majority of the run ( $67 \%$, Table 3); ages 1.2 (8\%) and 2.3 (18\%) sockeye salmon were also abundant. Scales were unreadable or regenerated for 141 (17\%) samples. Over all strata in 2006, $47 \%$ of the sockeye salmon sampled were females (Table 4). Sex composition varied by sample period and ranged from $42 \%$ females in stratum 2 to $60 \%$ females in strata 1

Table 3. Estimated age composition (\%) of sockeye salmon by stratum in Mortensens Creek, 2006. Data are only presented for age classes comprising more than $2 \%$ of the sample.

and 6. Lengths of sockeye salmon sampled in 2006 ranged from 427 to 581 mm for females, and from 420 to 626 mm for males (Table 5, Figure 6). In general, males were longer than females at a given age and the more winters a fish spent in the ocean, the larger its size.

## Discussion

Sockeye salmon escapement in Mortensens Creek ranged from 4,268 to 21,703 over the six years of the project, and met or exceeded the ADFG escapement goal $(3,200$ to 6,400$)$ every year (Table 2). Run timing past the Mortensens Creek weir was also variable over the duration of the project, with earlier run timing observed in 2002 and 2004 (Figure 7; Appendix C). The mean $50^{\text {th }}$ percentile passage over the six year period was 7 August; run timing in 2002 and 2004 was about two weeks earlier than average (Appendix C). Commercial harvest of sockeye salmon outside Mortensens Lagoon exceeded escapement past the weir in 2002 and 2003, although some fish harvested may not have been destined to spawn in Mortensens Creek (Table 6). Subsistence harvest in Mortensens Lagoon was greatest in 2003 and 2004, but was less than 20\% of the run in all years except 2000 and 2004 (Table 6). Residents of Cold Bay depend on subsistence harvest of sockeye salmon in Mortensens Lagoon more than other areas, while King Cove residents gather more subsistence sockeye salmon in places besides Mortensens Lagoon (Table 7). Less than 400 sockeye salmon were harvested in the sport fishery in $2002(n=104)$ and 2003 ( $n=360$ ) based on creel surveys (Whitton 2003; 2004). It appears that the sockeye salmon population in Mortensens Creek can be self-sustaining with current levels of subsistence and sport harvest, although the commercial fishery has the potential to overharvest this small run.

Age composition of sockeye salmon sampled at Mortensens Creek was consistent over the years except for 2004 (Table 8). Age 1.3 was the predominant age class of sockeye salmon observed at the weir, accounting for over two thirds of the run. In 2004, age 1.3 sockeye salmon were also dominant, but age 2.2 fish accounted for one fourth of the run; age 2.2 sockeye salmon were a minor component of the run in all other years. In all years except 2005, males were more common than females in Mortensens Creek (Table 8). Mean lengths of sockeye salmon by age varied over years (Table 9). Fish that spent three winters in the ocean were larger than fish that spent two winters in the ocean in all years regardless of the length of freshwater rearing.

Coho salmon escapement in Mortensens Creek ranged from 3,836 to 8,184 over the six years of the project, although a complete count was not obtained in 2006 (Table 2). Run timing past the Mortensens Creek weir was consistent in all years except 2002, when the $50^{\text {th }}$ percentile passage occurred about two weeks after the average for all other years (Figure 8; Appendix D). In most years, the majority of coho salmon passage in Mortensens Creek occurred in one or two large pulses of fish (Appendix D). Commercial and subsistence harvest of coho salmon outside Mortensens Lagoon has been minimal in recent years (Table 6), and sport harvest was less than 500 fish in $2002(\mathrm{n}=140)$ and $2003(\mathrm{n}=483)$ based on creel surveys (Whitton 2003; 2004). Current levels of harvest should have little impact on the coho salmon population in Mortensens Creek.

Age 2.1 coho salmon were the dominant age class in all years of sampling at Mortensens Creek, although age 1.1 fish comprised a greater percentage of the run in 2004 and 2005 compared to previous years (Table 10). We did not collect biological samples from coho salmon in 2006, so we do not know if this trend has continued. Males were more common than females at the weir

in all years except 2003 and 2004 (Table 10). Mean lengths of coho salmon by age were similar from 2001 to 2003, but fish were somewhat smaller in 2004 and 2005 regardless of age (Table 11). We did not measure lengths in 2006 to determine if this trend continued.

Although comparisons of motion detection files to continuous recording were nearly identical in 2006, no comparisons were done for hours of high fish passage. We have observed motion detection failures in other systems during higher fish passage rates ( 600 fish/h; Anderson et al. 2006), and motion detection file review at Mortensens Creek in 2006 was not effective at high passage rates (> 300 fish/h). Other motion detection systems designed specifically for video monitoring of fish passage have been used successfully. Hatch et al. (1998) developed a motion detection algorithm to detect the presence of fish on time-lapse video by comparing pixel luminance values between consecutive videotape frames. Counts of their source and edited video tapes were nearly identical, even during times of high fish passage ( $>400 \mathrm{fish} / \mathrm{d}$; Hatch et al. 1998). However, application of their technology has been problematic in some instances (Faurot and Kucera 2002), and other motion detection algorithms have also proven difficult to implement (Hetrick et al. 2004; Estensen and Cartusciello 2005). Passage rates at Mortensens Creek when the motion detection was not effective (> 300 fish/h) were well above the "high" fish passage density category (> $400 \mathrm{fish} / \mathrm{d}$ ) described by Hatch et al. (1998). Except for passage rates $>300 \mathrm{fish} / \mathrm{h}$, motion detection was capable of accurately monitoring fish passage at Mortensens Creek in 2006. However, potential bias of motion-triggered file review should be investigated at high fish passage rates.

A problem we have had with other video monitoring projects is erratic fish behavior at night, possibly a behavioral response to artificial white light (Anderson et al. 2006; Dion 2006). In some instances, fish would swim into the video monitoring chute and dart around rapidly passing upstream and downstream. On other occasions, erratic fish behavior in the video monitoring

${ }^{\mathrm{d}}$ Dion (2005)
${ }^{e}$ Hildreth and Dion (2006)
chutes during darkness would cause almost constant recording of motion-triggered files, resulting in near constant recording. This erratic behavior made it difficult to get accurate counts (Anderson et al. 2006; Dion 2006). At Mortensens Creek in 2006, the crew did not observe erratic behavior at night in response to artificial light, and most sockeye salmon passage occurred at night (Figure 3). The crew did observe that fish tended to mill about and swim through the video monitoring chute in both directions during slack tides, day or night, but this behavior did not affect the counts in 2006. The strong tidal influence on fish passage at Mortensens Creek might mask any effects artificial light has on fish behavior.

Based on data collected from 2001 through 2005, the KSFO did not attempt to extend funding of the Mortensens Creek weir past 2006. Sockeye and coho salmon populations in Mortensens Creek can continue to support harvest by all user groups at current levels, although the commercial fishery for sockeye salmon has the potential to overharvest this small run.

## Acknowledgements

The U.S. Fish and Wildlife Service, Office of Subsistence Management, provided funding support for this project through the Fisheries Resource Monitoring Program as project numbers FIS 01-206 (2001 to 2003) and FIS 04-402 (2004 to 2006); this report serves as the final project report for FIS 04-402. We thank T. Anderson, Z. Brock, and A. Filous for their outstanding efforts at the Mortensens Creek weir in 2006. We also thank staff at Izembek National Wildlife Refuge for logistical support. Finally, we thank Arnie Shaul, Joe Dinnocenzo, Daniel Doolittle, and Phillip Tschersich of the Alaska Department of Fish and Game for their assistance over the years.
