THE CONSEQUENCES OF INGESTION BY MAN OF REAL AND SIMULATED FALLOUT*

GEORGE V. LeROY, JOHN H. RUST and ROBERT J. HASTERLIK

Departments of Medicine and Pharmacology, The University of Chicago, and the Argonne Cancer Research Hospital, † Chicago, Illinois

(Received 19 April 1965; in revised form 1 July 1965)

Abstract—Real and simulated particulate fallout and solutions of $^{85}\text{SrCl}_2$ and $^{134}\text{CsCl}$ were fed to 102 healthy volunteers. Absorption and retention of ingested radioactivity was measured by whole-body counting using the gamma-ray spectrometer at the Argonne Cancer Research Hospital. An average of 3 per cent of the radioactivity of week-old local fallout was absorbed: the range was 0-9 per cent. Strontium and cesium leached or dissolved from simulated fallout behaved in the same way, metabolically, after absorption as they did when the tracer was swallowed in a solution or injected intravenously. The large number of subjects studied provided additional information on the range of variation of intestinal motility, biological availability of strontium, cesium and barium following ingestion of fallout, and retention of the radionuclides of these elements.

I. INTRODUCTION

IN 1961 CONCERN about some of the problems of the internal deposit of fission products (FP) following ingestion of local fallout led us to propose studies using real fallout from the Nevada Test Site (NTS); simulated fallout particles that contained ^{85}Sr , ^{133}Ba or ^{134}Cs ; and solutions of $^{85}\text{SrCl}_2$ and $^{134}\text{CsCl}$. The proposal involved feeding the test materials to healthy adult volunteers and estimating retention and absorption from measurements of their gamma radiation using the whole-body spectrometer (WBS) of the Argonne Cancer Research Hospital. The results reported here are concerned with the transit time of particles in the gastrointestinal tract (Section II); the biological availability of radioactivity following ingestion of real local fallout (Section III); and the extent to which the process of leaching from simulated fallout

may modify the metabolic behavior of strontium, cesium and barium (Section IV).

The fallout that we studied and attempted to simulate is designated variously as *local*, *early* or *close-in*. After land-surface detonations in the United States at the NTS such fallout consists of particles ranging in size from less than $1\ \mu$ in diameter to more than 1 mm. The particles are composed of FP, and soil materials and components of the nuclear device in which radioactivity has been induced by neutrons. Near the point of detonation the particles are large and siliceous with radioactivity distributed throughout and condensed on the surface. The ratio of biologically available activity to total radioactivity is reported to be small. As one moves away and downwind from the point of detonation the particles become smaller, relatively more of the radioactivity is condensed on their surfaces, and biological availability of the FP is increased. The extent of the distribution of fallout depends on the size of the nuclear explosion, meteorological conditions, and the relation of the fireball to the surface of the earth. With high-yield thermonuclear weapons under average weather conditions local fallout may extend to distances exceeding 500 miles, and the

area contaminated by a single weapon may exceed thousands of square miles.

The principal hazard from this variety of fallout is external exposure to gamma radiation, the intensity of which may exceed 1000 R/hr in some locations at the time when fallout is completed. The risk of internal deposition of FP is real but the magnitude of the risk is uncertain. Fallout particles enter the body by inhalation and ingestion. Because of the relatively large size of the particles, the majority of those inhaled are promptly trapped in mucus and quickly cleared from the respiratory passages either to be expectorated or swallowed. Fallout ingested with food or water (plus that from the respiratory tract) passes through the gastrointestinal system where the particles are exposed to a changing chemical environment in which some fraction of the FP may be dissolved and thus become available for absorption and subsequent deposition in internal organs and tissues.

The factors responsible for absorption of FP determine the biological availability of the radionuclides in fallout. These factors include: (1) the physical and chemical characteristics of the particles, i.e. the leachability and solubility of the nuclides they contain; (2) the absorbability of the chemical compounds formed in the intestinal contents; and (3) the transit time of particles through the gastrointestinal tract. Various estimates have been made of the biological availability in man of local fallout. According to *Effects of Nuclear Weapons*⁽¹⁾ 10 per cent of FP in local fallout is available, but there are no experimental data to support this estimate. MILLER⁽²⁾ has calculated the potential solubility of the principal nuclides as a function of particle size. In the case of ¹³¹I the estimate ranges from 0.016 (fraction soluble) for particles deposited close to the detonation, to 1.0 for the more distant ones. For ⁹⁰Sr, theoretical solubility ranges from 0.16 close in, to 1.0 at the outer limits of the distribution.⁽³⁾ The chemical solubility of local fallout collected at NTS after tests of various nuclear devices ranges from nil to more than 50 per cent. Some writers assume that biological availability parallels the chemical solubility in dilute solutions of acids. In some estimates of the hazard from ingested fallout the biological availability is taken as equal to the abundance of a particular radionuclide.

The possibility of obtaining suitable simulants for fallout occurred to us after reading a report that described the "radiating microspheres" developed by the Minnesota Mining and Manufacturing Co. (3 M). These are "ceramic bodies of spherical shape and selected size which contain and immobilize relatively large quantities of many useful isotopes". In reply to our inquiry, T. N. LAHR of the 3 M Radiochemical Project said that he could make microspheres in which a radionuclide would not be completely immobilized so that some fraction would leach out in a weak acid solution. In December 1961 two of us (JHR and GVL) met with a group of scientists interested in fallout at Atomic Energy Commission headquarters in Germantown. The group (KERMIT LARSON, J. Z. HOLLAND, W. Z. LOTZ, H. D. BRUNER, S. H. COHN and J. S. ROBERTSON) agreed that it should be possible to prepare satisfactory simulants with the following properties: the close-in simulant should be glassy or ceramic, and about 10 per cent of the radioactivity should be leachable; the distant simulant should resemble a sintered oxide with a solubility of about 70 per cent; a suitable particle size would be in the range 20-60 μ in diameter. In addition the group agreed that the proposed studies were feasible and worth doing, and that the elements of greatest interest were strontium, cesium and barium.

The radionuclides of these elements (and iodine) in FP are considered *critical nuclides* because metabolic processes lead to concentration in bone, muscle and the thyroid gland. Once concentrated, each turns over slowly so that the combination of selective deposition, long effective half-life (with the exception of ¹³¹I) and energetic nuclear radiations can result in a significant internal radiation dose. The estimate of internal dose following ingestion is based on assumptions regarding the fraction absorbed, the fraction of the amount absorbed that goes to the target organ, and the rate of removal from the target organ. For most purposes the values assigned to these assumptions are those given in *ICRP Publication No. 2*,⁽⁵⁾ and listed in Table I. Although these are convenient averages the fact is that absorption, concentration in a target organ, and biological turnover may be profoundly modified by such factors as the motility of the gastrointestinal tract, the chemical

compounds formed in the intestinal contents, the route of administration which may regulate the amount that goes to the target organ, and the physiological state of the individual.

There is an extensive literature on fallout,* most of which deals with (1) the external radiation hazard from local fallout; (2) the body burden of critical nuclides in animals collected near a test site; (3) the movement through the biosphere of critical nuclides from local as well as world-wide fallout; and (4) the metabolism of iodine, strontium and cesium following oral and parenteral administration of solutions, and after accidental contamination. We are not aware of any report of the feeding of real, local fallout to volunteers. To our knowledge this is also the first study where strontium, cesium or barium were administered in a fashion that simulated the actual ingestion of particulate fallout. Since it was debatable if there was any advantage to the use of simulants, an important objective of our study was to compare the behavior of radionuclides leached from the simulant with that of simple solutions of strontium and cesium.

* For a concise statement about fallout, see *Effects of Nuclear Weapons*;⁽¹⁾ for a more detailed discussion, see *Fallout and Radiological Countermeasures*.⁽²⁾

Plan of experiments and methods

The design of the experiments was simple: whole-body counting was used to measure the amount of γ -emitting activity that remained in the bodies of the volunteers at intervals after ingestion of the test materials. The real fallout and the simulants were swallowed in gelatin capsules; the solutions of $^{134}\text{CsCl}$ and $^{85}\text{SrCl}_2$ were swallowed with several ounces of water. All test materials were administered without regard to meals or times of day. The identity and the amount of the radionuclide in each dose was determined by one of us (GVL) before administration using an Autogamma γ -ray spectrometer. Immediately before the dose was taken, the body background of the subject was measured for 40–60 min in the WBS. At some time during the few hours following the dose—and before the subject voided—a 2-min whole-body count was made. The net counting rate at the time of the first post-dose count was taken as 100 per cent of dose for the purpose of calculating retention at later times. Thereafter, at intervals that varied from a few days to a few weeks serial whole-body counts were made: the counting time was adjusted to the amount of activity remaining so that the probable error of counting was small. Serial counts were continued until: (1) the net counting rate decreased to less than 1.0 per cent of the first post-dose count.

(2) sufficient counts were obtained for a reliable estimate of rate of excretion or (3) the volunteer was no longer available. In a few cases samples of stool and urine were collected during the first few weeks after simulants were fed, and these were measured in a properly calibrated large-volume well counter. The information from these measurements was not commensurate with the effort expended and collections of excreta were discontinued early in the study.

The volunteers were healthy adults—University students and members of our staff—who were properly informed of the nature of the experiments and the implications of the study for Civil Defense. None reported any gastrointestinal symptoms following ingestion of any of the test materials. The experiments were approved by the Committee for the Human Use of Radioisotopes of the University of Chicago Hospitals and Clinics. The total number of volunteers was 102.

All measurements of radioactivity retained in the subjects were made with the whole-body gamma-ray spectrometer (WBS) of the Argonne Cancer Research Hospital. This instrument, which has been described in detail elsewhere⁽⁷⁾ consists of four 5 × 5-in. thallium-activated NaI crystals coupled to photomultiplier tubes arranged above a couch in an iron-shielded room. The output of each crystal detector is transferred through a mixing circuit to a multi-channel pulse height analyzer adjustable for readouts of 3, 6 or 12 keV per channel. The readout is stored on punched paper tape. When the volunteers were counted the four crystals were placed approximately equidistant from each other along the midline of the subject and 18.5 in. above the couch. For one-half the counting time the subject was supine; for the other half prone. Preliminary trials demonstrated that there was only a few per cent difference in the efficiency with which the WBS measured a point source (such as a capsule) inside a subject's body and the same amount of activity distributed throughout the body as an extended source. The practice of counting in the prone and the supine position adequately compensated for any inequality in the anterior-posterior distribution of radioactivity in the course of an experiment.

The Argonne Cancer Research Hospital

instrument is very stable: twenty-two counts of a standard ⁸⁵Sr source (four vials containing a total of 0.57 μc) gave a mean of 12,398 ± 190 net cpm. Variations of the background of the iron-shielded room were equally small, and when contamination occurred it was cleaned up promptly.

The dead time of our WBS is corrected automatically by a proportional increase in the live time of the duty cycle. At counting rates less than about 500,000 cpm the response of the instrument is a linear function of the amount of radioactivity present. Since few of our counts exceeded 100,000 cpm no correction for coincidence was necessary.

The background counting rate of the iron-shielded room was measured each day by a 40- or 60-min count, and the performance of the detectors was checked using a sealed calibration source that contained 2.0 μg of ²²⁶Ra in equilibrium with its daughters.* The efficiency of the WBS for the various test materials and for the energy ranges used to count them is shown in Table I.2.

Processing the data

The fraction of dose retained at any time, t , days was

$$f_R^{(t)} = \frac{\text{net cpm at } t}{\text{net cpm at } t_0}, \quad (1)$$

where t_0 is the time of the first count after the dose was swallowed.

The fraction of dose absorbed, f_A , was obtained from serial whole body counts made during the second through the sixth week after the dose was given. We assumed that 99+ per cent of the ingested insoluble material was eliminated from the intestinal tract before the end of the seventh day (see Section II).

In the case of ¹³⁴Cs serial values for net counts corrected for decay were plotted on a semi-logarithmic chart and the y -intercept for day 1 (the day after the dose was given) was obtained by extrapolating a line fitted by eye for the period 1–7 weeks. For ⁸⁵Sr and ¹³³Ba serial counts were plotted

* Supplied by the National Bureau of Standards.

† The symbols f_R and f_A were selected because they do not duplicate any of the symbols used in I.2. Publication No. 2.⁽⁵⁾

§ Efficiency = $\frac{\text{net cps}}{\gamma\text{-photons/sec}} \times 100$. Photon yield for ¹³⁴Cs was taken as 0.8, for ¹³³Ba as 0.74, and for ²²⁶Ra as 1.0.

a log-log chart, and the γ -intercept for day 1 was read off the eye-fitted line. The fraction of dose absorbed was

$$f_A = \frac{\text{extrapolated net cpm at day 1}}{\text{observed net cpm at } t_0} \quad (\text{I-2})$$

Although it is the convention to assume that biological elimination of most elements follows a simple exponential function, it is well known that many data support the view that the fraction of the body burden excreted per day may vary inversely with time and may be best represented by a power function. Following a single injection of certain bone-seeking radionuclides—such as those of strontium and barium—the body burden can be expressed as

$$R(t) = At^{-n}, \quad t \geq 1 \text{ day}, \quad (\text{I-3})$$

where $R(t)$ = fractional retention t days after injection; A = normalized fraction of injected dose retained at the end of unit time; and n = a constant.

We have chosen not to employ this expression for individual subjects because there is some indication that a power function does not represent precisely the true situation, since the exponent n has been found to vary with time. In addition to this, its metabolic significance remains unexplained. For the sake of simplicity we expressed long term retention of strontium,

barium and cesium as the per cent of the amount absorbed (f_A) remaining in the body at times longer than 50 days. In the case of cesium where elimination appears to follow a simple exponential function indefinitely, the rate of elimination is reported as the half-time in days.

II. TRANSIT TIME OF PARTICLES THROUGH THE HUMAN GASTRO-INTESTINAL TRACT

It is common knowledge that the time required for some recognizable articles of the diet (corn, for example) to appear in the feces varies from a matter of hours to several days. In fact, the variation in intestinal motility of healthy people is so great that few clinicians will agree on an average time for half or all of a suitable indicator to pass through the gut. For radiological health purposes, most workers use the assumptions proposed for the Standard Man which are given in Table II.1. These were not particularly useful for our purpose since we were less concerned with the radiation dose to portions of the gut than we were about the time at which we could confidently expect that 99 per cent or more of ingested particulate material had been excreted. The Standard Man value—an average of 31 hr from ingestion to excretion—is obviously too short and does not provide any indication of the variability which must occur. We were interested in obtaining a reliable value

Table II.1. *The gastrointestinal tract of the standard man*

Portion of interest	Mass of contents (g)	Time food remains (hr)	Suggested revision* (hr)
Stomach	250	1	1
Small intestine	1100	4	4
Upper large intestine	135	8	13
Lower large intestine	150	18	31

* HAYES, CARLTON and BUTLER⁽⁸⁾ studied the elimination of an insoluble tracer and suggested changing the entrance time into the lower large intestine from 13 to 18 hr; and the in-residence time in the lower large intestine from 18 to 31 hr.

Source: Table 11, Report of Committee II, ICRP.⁽⁵⁾

for the 99 per cent excretion time because we could then assume that any radioactivity subsequently remaining represented nuclides released from particles and absorbed from the intestinal tract *minus* the fraction of absorbed activity excreted in urine and feces up to that time. Obviously it was to our advantage to start making serial measurements to estimate the rate of excretion of absorbed material as soon as possible after the dose was administered. In this report, then, we define *transit time* as the time required to excrete more than 99 per cent of a dose of insoluble material.

When we began this study the report of HAYES, CARLTON and BUTLER⁽⁸⁾ had not yet been published. The only guidance available to us was the experience of several groups of investigators with oral doses of ⁵⁹Fe to study iron absorption using whole-body counting. There was general agreement among them that all of the unabsorbed tracer was excreted by 10–14 days. The experiments reported here were designed to find a time between 31 hr and 10 days which would satisfy our requirements. In addition to information about the distribution of transit times we were interested to find out if any significant fraction of insoluble particles was trapped in anatomical features of the gut such as the vermiform appendix. Finally we wanted to know if the stable microspheres were as insoluble *in vivo* as *in vitro*.

Materials and methods

Radiating microspheres containing ⁸⁵Sr or ¹³⁴Cs or ¹³³Ba were prepared for us by the Radiochemical Project of the Minnesota Mining and Manufacturing Company to be used as insoluble controls for the simulants of fallout.

The microspheres are milky white in appearance and almost perfectly spherical in shape. They have an absolute density of about 3.0 g/cm³ and a bulk density of 2. They are completely ceramic in nature and have a melting point in excess of 1500°C. They are physically insoluble in all organic and inorganic solvents except boiling 57 per cent HF. Soak tests in water and in 0.01 N HCl for 7 days at 50°C demonstrated slight leaching of the nuclide label: on the order of 0.001 to 0.004 per cent.⁽⁴⁾ The specific activity was about 50 μ c/g, and the particle size was in the 30–40 μ range.

Three groups of volunteers—fourteen in all—were used for a pilot study to see if there was any retention of radioactivity at 10 and 20 days after ingestion of the labeled microspheres. On the basis of these results, three additional groups (a total of twelve) were fed ¹³⁴Cs-labeled microspheres and counted every 2 days until the amount of activity remaining was less than 0.1 per cent of the dose. Some of the subjects were asked to keep diaries recording their bowel movements: this information was less important than the counting data so the practice was discontinued.

The amount of radioactivity fed—from about 0.5 to 14.0 μ c—was a compromise: on the one hand we were obligated to keep the radiation dose to the gut to a minimum; and on the other hand we wanted to use sufficient activity so that retention of less than 1.0 per cent could be measured with an acceptable probable error.

Results

The counting data for the three pilot studies are shown in Table II.2. In Experiment No. 1 the amount of ⁸⁵Sr microspheres fed was

Probable error for $f_R = 0.01$ of dose: (1) ⁸⁵Sr = 55 net cpm; PE = 4.9 per cent, (2) For ¹³³Ba = 1200 net cpm; PE = 0.4 per cent, (3) For ¹³⁴Cs = 2330 net cpm; PE = 0.3 per cent. $PE = \frac{67.45}{\sqrt{G}} \left(\frac{\sqrt{K^2 + K}}{K - 1} \right)$, where G = gross counts; and $K = \frac{\text{gross cpm}}{\text{background cpm}}$.

Standard error of background rate: (1) For ⁸⁵Sr experiment = 17 cpm; (2) For ¹³³Ba experiment = 26 cpm; (3) For ¹³⁴Cs experiment = 21 cpm. $SE = \sqrt{\text{cpm}}$.

* Net cpm not corrected for decay; † f_R = fraction of dose remaining; ‡ nsc = No significant counts, i.e. equal to or less than background rate.

small that the probable error of the net counting rate (PE) if 1.0 per cent of the dose remained (e.g. about 55 net cpm) was 4.9 per cent. When the net cpm on D + 10 and D + 20 are corrected for decay it appears that the average retention was about 1.5 and 1.0 per cent of dose, respectively. From these data alone it is not possible to decide if the fraction that remained represents microspheres trapped in the gut, or radiostrontium leached from the supposedly insoluble microspheres and absorbed from the intestinal contents.

In Experiment No. 9 when larger amounts of ¹³³Ba microspheres were fed, the net counting rates on D + 11 and D + 23 were distinctly less than the standard error ($SE = \sqrt{\text{cpm}}$) of the background counting rate: 26 cpm. In this case we concluded that no microspheres remained in the gut, and that no ¹³³Ba had been leached from the particles and absorbed.

With the ¹³⁴Cs microspheres (Experiment No. 1) the fraction of activity remaining on D + 10 and D + 20 was less than in the case of

⁸⁵Sr but may be significant. The PE of these net counting rates was less than 5 per cent, and in every case the observed net cpm was several times the SE of the background counting rate: 25 cpm. Since it is unlikely that any microspheres remained in the gut as long as 20 days, we concluded that some radiocesium—less than 0.2 per cent—had leached from the particles and been absorbed. The net counting rates were so low, however, that it was not feasible to attempt an estimate of the fraction of leached material that was absorbed.

The pilot study was satisfactory because the results indicated that the upper limit of the distribution of transit times was less than 10 days.

The results of three additional experiments with ¹³⁴Cs microspheres are given in Table II.3. Here the findings are expressed as per cent of dose remaining on Days +2, +4, +6, +8 and +10. The data indicate that on the average about 60 per cent of the particles were excreted during the first 48 hr following ingestion. The range, however, was quite large: from 2 to 100

* To calculate averages, $<0.1 = 0.1$.

per cent remained. By the sixth day less than 0.1 per cent of the dose was still retained by ten of twelve subjects. Combining the results of these three experiments with those of Experiment No. 1 (Table II.2) we see that by the tenth day only three of seventeen subjects retained more than 0.1 per cent of the dose of ^{134}Cs . The actual values for these were 202, 593 and 895 net cpm, respectively, i.e. 0.19, 0.22 and 0.95 per cent of the dose.

Discussion

Our findings indicated that we could begin serial measurements in the WBS to evaluate absorption as early as the sixth day after the dose was swallowed if we were willing to accept a small amount of uncertainty because of individual variations. By waiting a day or two longer the likelihood became substantially less that any particulate material remained in the gut. Our results suggest that the Standard Man assumption of 31 hr as the average time that ingested material remains in the intestinal tract (Table II.1) is too short, thus leading to underestimates of radiation dose to the intestinal mucosa from ingested radioactivity. There does not appear to be any simple way to use the data obtained by whole-body counting to adjust the Standard Man assumptions.

It is interesting to compare the findings of HAYES *et al.*⁽⁸⁾ with those presented here. They fed an insoluble tracer, ^{140}La citrate, to fifty-four patients and measured the radioactivity in each stool as it was passed. For each subject at least 90 per cent of the dose was recovered ultimately. A graph from their report showing cumulative excretion as a function of time after ingestion is redrawn as Fig. II.1. On the same figure there is a comparable curve showing the average fraction of dose remaining in our subjects. HAYES *et al.*⁽⁸⁾ state that for radioactive material with a half-life longer than about 12 hr the Standard Man assumptions require revision. An average residence time of 49 hr fits their data better than the published value: 31 hr. Reading the points off their curve (Fig. II.1) it appears that about 60 per cent of the activity was excreted during the first day; and the time for 98 to 99 per cent excretion was about 4 days. It is evident that bowel motility was somewhat more rapid in their patient-subjects than in our healthy active volunteers. Perhaps bowel habits are more regular in hospital than elsewhere. Actually the difference in intestinal motility between the two groups is not very important. Had we used their data to determine the time when less than 1 per cent of the dose of insoluble material remained in the gut we would have selected 11

FIG. II.1. Transit time of particles in the human intestinal tract. The upper curve is the cumulative excretion of ^{140}La citrate by hospitalized subjects whose median age was less than 53 years. This curve is redrawn from HAYES, CARLTON and BUTLER.⁽⁸⁾ The lower curve is the average for twelve of our subjects who received ^{134}Cs -microspheres (Table II.3).

fifth or sixth day. On the basis of the results presented here we waited about 48 hr longer before we assumed that excretion of insoluble particles was complete—that is, that less than 1 per cent of the dose remains.

The 3 M stable radiating microspheres were described by the manufacturer as insoluble. Some leaching occurred *in vitro*, however, when tracer-labeled microspheres were submitted to a soak test. In the case of ^{137}Cs and ^{90}Sr microspheres, for example, the manufacturer reported that the leach rate was the same in water and in dilute HCl. In prolonged tests "leaching continues at a constant rate after 7–14 days, and is independent of sample size and solvent volume within reasonable limits."⁽⁴⁾ Our data suggested that more leaching occurred in the intestinal contents of man than *in vitro*. After 7 days it appeared that about 1 per cent of ^{85}Sr had been retained. In other experiments (see Section IV) when a dilute aqueous solution of $^{85}\text{SrCl}_2$ was fed the fraction absorbed was about 17 per cent. Such being the case it is proper to assume that as much as 4 or 5 per cent of the radiostrontium leached out of the "stable" ^{85}Sr microspheres during their residence in the gut. This is much

more than the 0.001 per cent reported for soak tests using ^{90}Sr microspheres prepared in the same fashion as the ones we used. Our own soak tests (Table IV.1) were performed with 0.1 N HCl and 0.1 N NaOH at 37°C for 2 hr. No measurable activity was leached from any of the stable microspheres. The procedure used could detect at least 0.001 per cent of the activity present. We have no information about the physiological mechanisms that are responsible for the discrepancy between the *in vivo* and the *in vitro* results.

When solutions of $^{134}\text{CsCl}$ were fed (see Section IV) about 90 per cent of the tracer was absorbed. The amount of radiocesium leached from the ^{134}Cs microspheres and absorbed ranged from about 0.03 to 0.2 per cent. This is significantly more than the 0.004 per cent leached *in vitro* reported by the manufacturer for ^{137}Cs microspheres manufactured in the same fashion as those supplied to us.

The radiation dose to the lower large intestine was calculated using 31 hr as the average residence time. The largest dose was 696 mrad, and the average was less than one-half that amount. The estimates of radiation dose for all experiments are given in Table II.4.

III. THE AVAILABILITY OF RADIO-NUCLIDES IN LOCAL FALLOUT

The biological availability for man of the radioactivity contained in local fallout is not well documented. The factors that determine availability include: (1) the physical and chemical characteristics of the particles, i.e. the leachability and solubility of the nuclides they contain; (2) the absorbability of the chemical compounds formed in the intestinal contents; and (3) the transit time of particles through the gut. It is customary to assume that 10 per cent of the activity of local fallout that is swallowed is available. Measurements of the fraction of activity leached by acid, alkaline and neutral solutions have been reported that range from none to more than 50 per cent. Such data display wide variations depending on particle-size, solvent, age of the material, duration of contact with the solution, and conditions associated with the nuclear explosion. The present study was undertaken to measure the biological availability of activity in local fallout collected at a single

location following the land-surface detonation of a nuclear device: SMALL BOY, on 14 July 1962 at the Nevada Test Site of the United States Atomic Energy Commission.

Material and methods

The samples of fallout were sent to us by CARL F. MILLER (Stanford Research Institute) with the approval of the Office of Civil Defense. The material we received on D + 5 had the characteristics shown in Table III.1A. For the feeding experiments only samples No. 4, 5, 6, 7 and 8 were used. According to MILLER the fallout was collected at a distance of 4500 ft (1390 m) east of the site of detonation. The radiation intensity of the fallout field at that location, corrected to H + 1 hr was 34 R/hr. There were no measurements of the solubility of the samples we received, but data are available for other collections at nearby stations. These are also given in Table III.1B.

Portions of each sample were placed in soft gelatin capsules (dissolving time in stomach less than 10 min) to be swallowed by the volunteers,

or used to estimate the decay correction factor for the sample. At the time of ingestion (D + 5, D + 7, or D + 9) the gross gamma activity of each dose was equivalent to about 10^5 disintegrations/sec. This amount of activity was selected because: (1) we assumed acid-solubility was about 10 per cent; (2) we assumed the factor for the decay rate was approximately $t^{-1.2}$; (3) the beta:gamma ratio was taken to be unity; (4) we did not want the radiation dose to the lower large intestine to exceed 100 mrad;* and (5) we wanted to give enough activity to provide reliable counting rates during the third and fourth weeks after ingestion.

For these studies the output of the WBS was summed for the energy range 0.096 to 1.250 MeV. In this range the efficiency of the WBS is 0.95 per cent for ²²⁶Ra (see Table I.2), and presumably is the same for FP. When the subjects were counted the crystal arrangement was

* To approximate this dose we followed DUNNING who calculated that 48 μc of 1-day old fallout would deliver about 1.0 rad to the lower large intestine.

Another sample from the same location, was tested when 1.1 days old: acid-solubility ranged from 20 to 58 per cent.

as described in Section I. When the samples were counted the crystals were arrayed in a cluster directly over the source. Correction factors for radioactive decay were obtained by counting each sample at frequent intervals between D + 11 and D + 39. These measurements, corrected for background, are shown as a log-log plot in Fig. III.1. The curves which are linear, were fitted by eye and extrapolated back to the time the fallout samples were fed. A decay correction factor for each subject was obtained in the following manner: If the sample was fed on D + 6 the corresponding value for net cpm was read off Fig. III.1 (see the arrows on Curve No. 7) at the midpoint between 6 and 7 days (315,000), and the 14-day value was read off at the midpoint between 20 and 21 (66,000). The factor used in the case of LO was (315,000/66,000) 4.8. Individual decay factors were calculated for each sample and for the time period involved in each experiment.

Results

Net counting rates for the first count after ingestion of the samples are shown in Table III.2. The gamma-ray spectra for four of the five samples used are shown in Fig. III.2 (a satisfactory curve for Sample No. 4—the largest sized particles—is not available). There are minor differences among these spectra which may be due to variations in nuclide composition associated with particle size. The spectrum for Sample No. 6 has a prominent peak at about 1.2 MeV (yttrium-91,?) which is not evident in the others. Additional evidence for variation in composition of the different sized samples is seen in Fig. III.1, the graphic representation of the decay rates.

The results of the measurements of all ten subjects are summarized in Table III.2. The values for f_R —the fraction of dose retained on the last day—represent the amount of activity absorbed from the gut minus the fraction of

FIG. III.1. Decay rate of samples of real fallout.

FIG. III.2. Gamma-ray spectra after ingestion of real fallout. The counts for these spectra were summed for 12 keV/channel. The upper four curves were obtained 1-2 days after fallout was ingested. The lower spectrum (GA) is from a control subject and is included to demonstrate the resolution of the WBS. Background has not been subtracted from any of these spectra.

absorbed material that was excreted up to the time of the final count. The values for f_A —the fraction of dose absorbed—were estimated from f_R multiplied by an arbitrary constant, $c = 1.35$. This constant was derived from our study of simulated fallout that is described in Section IV. Using simulants labeled with ^{86}Sr or ^{134}Cs , f_A was obtained by extrapolation to Day + 1 of the curve for f_R versus time for the period 7–50 days after the simulant was swallowed. The relationship: $f_A = c \times f_R$ at 14 days, was determined. For ^{86}Sr , $c = 1.56$; and for ^{134}Cs , $c = 1.13$. We used the average, $c = 1.35$, to estimate f_A for the real fallout. The average amount of dose absorbed, 3.2 per cent ($f_A \times 100$), was much less than we expected and even the largest value—8.8 per cent in the case of —was smaller than the amount customarily assumed. In two cases— and —the final counting rate for all energies was the same or less than the subject's 60-min background count (nsc) and in these cases we have assumed that no activity was absorbed.

On the last day of the experiment the highest counting rate for all energies was 348 net cpm for on D + 20. The probable error of this rate is 1.5 per cent. The lowest final count—11 net cpm for on D + 22—has a PE of 34 per cent. Several subjects were counted again a few weeks later, but in every case the rate was not significantly different from the background count.

Discussion

Our findings demonstrate some of the vicissitudes encountered in a study of the consequences of ingestion of week-old siliceous local fallout. These include: (1) variations in the size and the nuclide-content of the particles; (2) rapid radioactive decay; (3) uncertain correlation between chemical solubility *in vitro* and biological availability as measured by the fraction of activity absorbed; (4) biological variability in the function of the human gut; and (5) the limitations of whole-body counting. In spite of these difficulties and the attendant uncertainties, the information obtained provides a better basis for evaluation of the relative hazards of ingestion of local fallout than is possible by indirect methods and studies of wild animals.

When the samples were received on D + 5

we had no information about their composition: we only knew that the material was local fallout from land-surface detonation and that the particles had been sorted into several categories of size. Standard references allow one to make an educated guess about the relative abundance of FP at the time the samples were fed. The complex decay pattern of FP mixtures makes analysis of the γ -ray spectrum difficult even under the most favorable circumstances. The spectra obtained with the WBS after ingestion (Fig. III.2) are further complicated by mass absorption effects, Compton scattering, and uncertain geometry. Under the conditions of our study it was not feasible to analyze rigorously such spectra. Division of the output of the WBS into arbitrarily selected energy ranges was tried and was not particularly helpful. When the final counts of the volunteers were tabulated on the basis of energy range (see Fig. III.2), range B was the only one where there were significant net counting rates for each subject. Since this range includes the principal photopeak of ^{131}I it is tempting to attribute the average of 31 net cpm to that radionuclide. If we do this we can estimate that most of the ^{131}I that should have been in these samples of local fallout was available for absorption.*

It appears from the data in Table III.2 that there was no correlation between availability and particle size: in each size-class there was a low value for f_R and a high one. As mentioned above we had no information about the solubility of the samples we received, although fallout collected nearby was found to have solubilities ranging from 3 to 42 per cent in HCl at pH 1.0 (see Table III.1B). It is customary to assume that the average solubility of local fallout is

* The amount of activity ingested was about $2.0 \mu\text{c}$: the abundance of ^{131}I between D + 7 and D + 15 is approximately 0.07. If all the ^{131}I was absorbed and the fraction retained in the thyroid was 0.3, then there should have been $2.0 \times 0.07 \times 0.3 = 0.042 \mu\text{c}$ (42 nc) in the gland shortly after the dose was swallowed. Assuming an effective half-life of 7 days, on the last day of the study there should have been about 10 nc in the thyroid. If all the counts in energy range B were indeed ^{131}I , and if the efficiency of the WBS was about 0.005, then $31/0.005 = 6000$ dpm, or about 3 nc at the time of the final count.

10 per cent, and that biological availability is of the same order. Our findings suggest that availability, on the average, is about 3 per cent of the total γ -emitting activity. Only four of ten subjects retained more than 3 per cent when measured 2 weeks after fallout was ingested, and two had almost none.

The interval of 2 weeks between feeding and the first examination in the WBS to assess absorption was chosen because we believed that some insoluble material might remain in the gut for as long as 10 days. The studies described in Section II were performed after these experiments with real fallout; and they indicated that retention of insoluble particles (30–40 μ in diameter) after the sixth or seventh day was the exception. Our experience with real fallout would have been more satisfactory had counts been made at 8, 10, 12 and 14 days instead of just at 14 days. Unfortunately we did not anticipate that the fraction retained would be as small as it was, so that we planned to obtain a series of measurements between the fourteenth and twenty-eighth day after feeding. For the twenty-eighth day after D + 6 the decay correction factor—using $t^{-1.2}$ —was about $\times 25$, and we expected to find counting rates during the fourth week on the order of 100 net cpm for all energies. Better data could have been obtained with larger doses, but we believed that we were obligated to limit the exposure of the lower large intestine to about 100 mrad.

IV. STUDIES WITH SIMULATED FALLOUT

Our experiments with simulated fallout were designed to answer the question: Does the fact that radionuclides of strontium, cesium or barium are released slowly into intestinal contents from real or simulated fallout modify their metabolic behavior during and after absorption from the gut? A corollary to this is the related question: Is it really necessary to use simulants to study the metabolism of critical nuclides from ingested fallout? There does not appear to be any good reason to ask these questions in the case of the radioisotopes of iodine since there is abundant evidence that soluble salts of iodine are absorbed rapidly from any portion of the gut. There is also good evidence that the fraction of iodine in the blood

that is trapped by the thyroid gland is not influenced by the manner in which the element enters the blood. There are, however, several reasons for asking the questions about strontium, cesium and barium: First, there are many gaps in our understanding of intestinal absorption of the familiar mineral elements that are classed as essential. The situation with respect to strontium—which also surely applies to cesium and barium—was epitomized by J. F. LOUITT (11) in 1961: "How strontium . . . (is) absorbed from the gut is still a matter of considerable debate; indeed is the whole subject of intestinal absorption. What appears to be certain is that not only the small intestine which absorbs these ions, but the rate is greater in the uppermost part of the long tract, though the greater mass may be absorbed down where the flow is much slower. Later in the same lecture he speculated that "the time-course of entry of strontium into circulation may affect its fate". And second, although we have no satisfactory data, it is reasonable to suppose that the leaching of radionuclides from siliceous local fallout in a changing chemical environment of the gut is a relatively slow process. The same is also probably true for the rate at which the sinter oxides of distant fallout dissolve in intestinal contents. Lacking many facts we will not be far wrong if we assume that dilute solutions of salts of strontium, cesium and barium are immediately available for absorption after they are swallowed, while compounds formed in the intestinal contents from radionuclides leached or dissolved from particulate fallout may be somewhat less available. In these circumstances it is appropriate to wonder—as LOUITT did—whether the time-course of absorption does affect the fate of critical nuclides. If it can be shown that there is indeed no significant difference in the rate of elimination of strontium, cesium and barium regardless of how they gained entrance to the blood, then valid studies of metabolism can be performed using the intravenous route for administration to avoid the inevitable uncertainties associated with experiments where the tracer is given by mouth.

Materials and methods

In accordance with the recommendations of our *ad hoc* advisors (see Section

Radio-chemical Project of the Minnesota Mining and Manufacturing Company prepared two types of simulants with the following characteristics.

Local simulant (LS) was a specially prepared microsphere fabricated from leachable glass that contained tracer amounts of ^{85}Sr , ^{134}Cs or ^{133}Ba . The material was manufactured so that about 10 per cent of the radioactivity could be leached from it by 0.1 N HCl at 37°C in 2 hr. The activity was approximately 50 $\mu\text{c/g}$, and particle size was in the 30–40 μ range. Although not entirely carrier-free, the amount of carrier was small.

Distant simulant (DS) was either strontium oxide + $^{85}\text{strontium oxide}$, or cesium silicate + $^{134}\text{cesium silicate}$, or barium oxide + $^{133}\text{barium oxide}$ calcined at about 900–1000°C. The calcined mass was pulverized and particles in the 30–40 μ range were used. The solubility specified was from 50 to 100 per cent in 0.1 N HCl. The specific activity of the DS was about 50 $\mu\text{c/g}$ at the time of preparation. In contrast to the LS the amount of carrier was relatively large.

Soak tests were performed by adding a few milligrams of simulant to 10 ml of 0.1 N HCl or 0.1 N NaOH in test tubes. The tubes were agitated constantly in a water bath at 37°C for 2 hr. After filtration the filtrates were counted in a well-type scintillation spectrometer (Auto-gamma). The results are shown in Table IV.1.

Solutions of $^{85}\text{SrCl}_2$ and $^{134}\text{CsCl}$ were prepared from carrier-free material using water as the

diluent. No effort was made to obtain a soluble salt of barium for these studies.

The range of doses administered is shown in Table II.4. The amount of radioactivity fed was a compromise: we wanted to keep the radiation dose to a minimum, and we wanted enough activity absorbed to permit reliable whole-body counting for several hundred days. We assumed that biological availability paralleled solubility and that the particulate nature of the material had no influence on availability. All doses were given without regard to meals or to time of day.

Results

The γ -ray spectra of three subjects who had ingested one or other of the radionuclides are shown in Fig. IV.1. The portions of the spectrum over which counts were summed for measurement of the whole body counting rate are indicated in each case, (See also Table I.2.)

Strontium-85. The solution of $^{85}\text{SrCl}_2$ was fed to twelve subjects; the average per cent of dose absorbed ($f_A \times 100$) was 17 with a range of 8–34 per cent (see Table IV.2). The rate of elimination of the fraction of dose absorbed was such that the average retention after 2 weeks was 52 per cent with a range of 34–77. At 50 days average retention decreased to 36 per cent (range: 17–65); after 100 days it was 26 per cent (range: 18–30); and after 150 days only an average of 19 per cent remained (range:

Table IV.1. Availability of radionuclides from simulants on the basis of soak tests

Simulant	Per cent leached or dissolved in:*		Average per cent absorbed by subjects ($f_A \times 100$)
	0.1 N HCl	0.1 N NaOH	
LS- $^{85}\text{Sr}\dagger$	6.0	8.0	16
DS- $^{85}\text{Sr}\ddagger$	72.0	15.0	13
LS- ^{134}Cs	1.4	5.0	31.0
DS- ^{134}Cs	38.0	12.0	82.0

DS- ^{133}Ba	91.0	23.0	6.0

*After soaking for 2 hr at 37°C.

† The soak test results refer to the second batch; the per cent absorbed by subjects refers to the first batch.

‡ All results apply to the second batch. Soak tests were not performed with the first batch, the average absorption of which was 32 per cent.

FIG. IV.1. Gamma-ray spectra after ingestion of simulants. The counts for these spectra were summed for 6 keV/channel. The heavy portion of each of the top three indicate the energy range over which counts were summed to measure retention. The bottom spectrum was obtained in February 1963 before the ^{133}Ba simulant was fed (spectrum directly above). The two small peaks in the third spectrum (^{133}Ba) at about 0.600 and 0.780 MeV are thought to be due to a trace of ^{134}Cs that contaminated the $\text{BaO} + ^{133}\text{BaO}$ during manufacture. After about 100 days these peaks were no longer seen.

6-24). The trials were not all of the same duration because of factors beyond our control such as vacations, graduation and dropping out of school. The lowest value for the final total body count in this group was 46 net cpm, not corrected for decay (subject 13.2 on D + 135). The PE of this net counting rate is 5.8 per cent.

The first batch of LS labeled with ^{85}Sr was fed to two groups of volunteers but only the first group yielded satisfactory data. As shown in Table IV.3 an average of 16 per cent of the activity was absorbed ($f_A \times 100$) and the range varied by a factor of 4—from 6 to 25 per cent—as was the case when the solution of $^{85}\text{SrCl}_2$ was fed. A second batch of LS was fed to four subjects but the fraction absorbed was no more than a few per cent and was very little different from that found when stable microspheres were fed (see Section III). This result was surprising because our soak tests showed that about 6 per cent of the activity was leached in 0.1 N HCl and 3 per cent in 0.1 N NaOH.

The first batch of DS was fed to five subjects (Table IV.3) and an average of 32 per cent of the activity was absorbed, with individual values that ranged from 21 to 47 per cent. When the second batch was fed less activity was absorbed: the average was 13 per cent. The soak tests of the second batch showed that acid solubility was 72 per cent. (The solubility of the first batch of DS was not measured but the specifications called for a solubility in this range.) A statistical test* showed no significance to the difference between the average f_A for the second batch of DS, the second batch of LS, and the

* The test used was the WILCOXON two-sample test⁽¹²⁾ in which the normal variable, K , is determined from the rank order of the individual measurements of two samples: $K = \frac{2R \pm 1 - n(N+1)}{n(N+1)(N-n)/3}$ where R = sum of the ranks of the smaller sample; N = total number of cases; n = number of cases in the smaller sample.

solution of chloride. When the results with the first batch of DS (average $f_A = 0.32$) were compared with all the others the difference was highly significant: $P = 0.004$.

After absorption of ^{85}Sr from the gut the rate of elimination was evaluated on the basis of per cent retention at 14, 50, 100 and 150 days. In practice, the measured values for activity retained were plotted as net cpm corrected for

FIG. IV.2. Unexpected variations after ^{85}Sr and ^{133}Ba . The topmost curve—DS- ^{133}Ba —is subject No. 1, Table IV.5, who absorbed the largest amount of barium. The curve for LS-2, Table IV.3 shows what we expected to find on serial counting to measure retention of ^{85}Sr . The other three curves demonstrate unexpected variations which—like those in the top curve—could not be attributed to malfunction of equipment or other errors.

decay on log-log paper. The value for f_A expressed in net cpm was entered on the ordinate for Day 1. Net counting rates for Days 14, 50, 100 and 150 were read off the curve and expressed as per cent of the extrapolated value for Day 1. The statistical test showed no significant difference between retention of activity from the chloride solution, LS, or the second batch of DS. These data therefore were combined and plotted as open circles on Fig. IV.4. The average for retention of ^{85}Sr from the first batch of DS are indicated by closed circles. The range of values within the various groups was so great that any distinction between the sources

was of doubtful significance. Accordingly the median value for per cent retention by all subjects receiving ^{85}Sr at 14, 50, 100 and 150 days was plotted as the crosses on Fig. IV.4. The line fitted by eye to these points intersects the abscissa at about 1.5 days. This is a reasonable time for absorption to be complete. The equation for this line is: $R(t) = 60 t^{-0.2}$, $t \geq 1$ week. This relationship predicts that after 52 weeks retention of ^{85}Sr will be approximately 16 per cent.

An unexpected increase or decrease in the whole-body counting rate occurred at some time among the serial measurements of sixteen of the thirty-five subjects who received ^{85}Sr . Some of these are illustrated in Fig. IV.2 where net counting rates corrected for decay are plotted against time in days on log-log coordinates. Initially, we supposed that these abnormal counts were caused by malfunction of the equipment and discontinued measurements of those subjects. When careful review of the operation of the WBS failed to provide an explanation for the majority of the abnormal counts the practice of terminating experiments where they occurred was stopped. The same phenomenon was observed when DS- ^{133}Ba was used (see below), but there were only occasional unexpected variations of the counting rates with any of the ^{134}Cs tracers, and none with any of the standard sources used to validate the performance of the instrument.

Cesium-134. The solution of $^{134}\text{CsCl}$ was fed to four volunteers who absorbed ($f_A \times 100$) 90, 90, 89 and 87 per cent respectively. When the LS was fed, absorption was 36, 29 and 29 per cent, respectively. In our soak tests of the LS about 2 per cent of the activity was leached in 0.1 N HCl at 37°C in 2 hr, and 5 per cent in 0.1 N NaOH under the same conditions. With the DS the average absorption for five subjects was 82 per cent. The solubility of the sintered ^{134}Cs silicate in our soak tests was 38 per cent in acid and 12 per cent in alkali. In all of the subjects who received ^{134}Cs the rate of elimination of the fraction of dose absorbed followed a single exponential function for as long as measurements of f_R were made. Table IV.4 gives the values for f_A , and for rate of elimination expressed as the half-time in days. The mean half-time (T_b) for the twelve subjects was 91 days.

Table IV.4. Biological turnover of ^{134}Cs

Subject	Tracer used	f_A	Measured half-life (days)	Half-life corrected for decay* (days) T_b	Duration of test (days)

* $T_r = 840$ days.

13 days. The elimination rate was not influenced by the form in which the tracer was administered: the results were the same for the solution and the particles ($P = 0.40$).

Barium-133 The local simulant labeled with ^{133}Ba was fed to three subjects: in one case retention ($f_R \times 100$) of approximately 1.0 per cent was found on the tenth day, but 11 days later no activity could be detected. On our soak tests 5 per cent of the activity was leached from the LS in 0.1 N HCl, and 0.7 per cent in alkali. The DS was fed to eight subjects, four of whom retained more than 1.0 per cent of the dose at the tenth day. The data for these four are given in Table IV.5. Absorption ($f_A \times 100$) was 15, 6, 3 and 1 per cent, respectively. Elimination was slow and at 100 days the amount

retained was 46, 33 and 42 per cent, respectively. In our soak tests the solubility of the DS was 91 per cent in acid and 23 per cent in alkali. Three of the four subjects who received the DS displayed unexpected variations in the serial counts which were as marked as in the case of those tested with ^{85}Sr (see Fig. IV.2).

Dose from internal radiation. Estimates of the internal radiation dose received by the volunteers are given in Table II.4. The largest dose to the lower large intestine—696 mrad—occurred when the stable ^{134}Cs microspheres were used to study transit time. This is about one-half of the maximum permissible internal dose to a single organ (1.2 rem in any 13-week period) according to the recommendations of ICRP for persons in Exposure Category B. The average

Table IV.5. Retention of ^{133}Ba released from distant simulant

radiation dose to the LLI from ^{134}Cs was probably less than 300 mrad. The largest whole body dose was also supplied by ^{134}Cs following absorption from the DS: approximately 165 mrad, using $T = 70$ days. This is about 1/10 of the maximum permissible internal dose recommended by ICRP for persons in Category B. The largest radiation dose to bone + bone marrow was 18 mrad from $^{85}\text{SrCl}_2$, using $T = 65$ days.

Discussion

The principal objective of these experiments was to answer the question: Does the fact that radionuclides of strontium and cesium are released slowly into intestinal contents from real or simulated fallout modify their metabolic behavior during and after absorption from the gut? As a preliminary it was necessary to feed solutions of the chloride salts to obtain baselines for comparison of the time-course of elimination of radioactivity leached or dissolved from particulate simulants. Although we have no data to support the assumption, we assumed that absorption of the solutions occurred rapidly and predominantly in the upper small intestine, while absorption of leached or dissolved activity occurred slowly from more distal portions of the gut where the in-residence time of the simulant was relatively long (see Table II.1). The null hypothesis that we tested can be stated as follows. The metabolism of strontium and cesium that enters the blood from the intestinal tract is not affected by the site at which intestinal absorption occurs nor by the rate of absorption. Our results support the null hypothesis since we found that the rate of elimination (or retention as a function of time) was not significantly different, whether the tracer was given in solution or as a particulate simulant. To evaluate the significance of such differences as were observed we used the WILCOXON two-sample test which is based on the rank order of the results rather than their means and standard deviations. On the basis of our findings we conclude that it is not necessary to use simulants to study the behavior of FP absorbed from ingested fallout.

Although we did not administer either ^{85}Sr or ^{134}Cs by intravenous injection the results we obtained for rate of elimination after intestinal absorption were sufficiently similar to those

reported in the literature for intravenous injection to warrant the conclusion that the parenteral route is satisfactory for most studies of the metabolism of these elements. This is an important conclusion since the parenteral route has obvious advantages over the oral, the chief of which are that the amount of activity entering the blood can be known with certainty, and that zero time is definite.

Even though our principal objective was to examine the need to use simulants to study internal deposition of FP from fallout, considerable information was obtained about two aspects of the metabolism of strontium, cesium and barium: intestinal absorption and retention in a small group of healthy active adults. In addition, our findings demonstrate some of the problems encountered when the metabolism of bone-seeking radionuclides is investigated by whole body counting. We shall consider each element in turn.

Cesium. The metabolism of cesium has been studied by many investigators: after accidents with ^{137}Cs , and after parenteral and oral administration of salts of ^{134}Cs and ^{137}Cs .⁽¹³⁾ The values reported for biological half-time (T_b) range from 65 to 135 days. Cesium chloride is readily absorbed, and our results ($f_A = 0.90$ for the chloride, and 0.82 for the oxide) are in good agreement with those reported by others. There is general agreement that a single exponential function is adequate to express the rate of elimination. In our group of twelve subjects (Table IV.4) the time of disappearance of one-half of the ^{134}Cs absorbed ranged from 70 to 129 days with a mean of 91 and a standard deviation of ± 18 days. The extreme values ($T_b = 70$ and 129 days) were found in the two longest experiments: 207 and 163 days, respectively, after taking $^{134}\text{CsCl}$. Although the series is not large it affords a good estimate of the biological variability of the excretion of cesium: coefficient of variation = 0.20.

Since most of the radiocesium is in muscle and soft tissue the efficiency with which the whole body detectors can "see" it should change little—if at all—with time. In all twelve cases the time course of retention was quite regular, and only in the two shown in Fig. IV.3 was there any unexpected deviation of the net counting rate.

Strontium. There are many reports in the

FIG. IV.3. Unexpected variations after ^{134}Cs . These are the only two instances among more than sixty whole-body counts where the result deviated significantly from the value expected. Except for the abnormal value in each curve, elimination followed a single exponential function.

literature about the metabolism of strontium using the stable isotope as well as ^{85}Sr , $^{87\text{m}}\text{Sr}$, ^{89}Sr and ^{90}Sr .⁽⁹⁾ In *ICRP Publication No. 2* (see Table I.1) the value for f_1 —the fraction entering the blood from the gastrointestinal tract—is given as 0.3. In twelve of our subjects fed the solution of $^{85}\text{SrCl}_2$ the average fraction absorbed (f_A) was 0.17 with a range 0.08–0.34. COHN, SPENCER, SAMACHSON and ROBERTSON⁽¹⁴⁾ reported absorption of 20.7 and 16.4 per cent, respectively, by two patients with osteoporosis. SPENCER *et al.*,⁽¹⁵⁾ using ^{90}Sr in contaminated food as the tracer, found a mean absorption of 15.3 ± 3.01 per cent in a group of twelve young volunteers. LOUITT⁽¹¹⁾ believes that “around 20 per cent seems to be a fairly representative figure to take for absorption of soluble strontium salts”. It is of interest that when he gave 100–200 mg of strontium as a soluble salt in water, some 35 per cent was absorbed. He attributed the larger absorption under these conditions to a mass effect. In our study, the largest value for f_A (0.47) was found in one of the subjects who received the first batch of the DS which contained abundant carrier SrO . The biological variability of absorption of strontium is thus much greater than that for cesium. When we fed

$^{85}\text{SrCl}_2$ absorption ranged from 8 to 34 per cent, and in the entire group of subjects the range was 6 to 47 per cent. If we set aside the five subjects who received the first batch of DS because their average absorption was significantly different from all the others ($P = 0.004$), then we can treat the remaining twenty as a sample that received tracer amounts of strontium. For this group, the mean absorption was 16.4 ± 7.9 per cent, and the median was 14.0 per cent. The coefficient of variation, 0.48 is greater than that reported by SPENCER *et al.*⁽¹⁵⁾; and is also much larger than that for cesium.

The general agreement about the extent of absorption of strontium from the gut does not extend to retention. Reports in the literature vary so greatly that it is not possible to cite a consensus. Biological half-life is often an ambiguous concept and the wide range of values reported for Sr turnover may be due in part to imprecise definition of the term. Using an exponential model COHN *et al.*⁽¹⁴⁾ reported biological half-times ranging from 210 to about 1000 days. LOUITT⁽¹¹⁾ estimated that about one-seventh of a dose of strontium is due for slow turnover along with the bone in which it is incorporated. He calculated the rate of bone

FIG. IV.4. Long-term retention of ^{85}Sr absorbed from gut. The open circles (O) are averages for retention by twenty subjects who received either $^{85}\text{SrCl}_2$, LS, or the second batch of DS. The closed circles (●) are the averages for the five subjects who received the first batch of DS. The median of the values for retention by all twenty-five subjects is indicated by the crosses (+).

replacement as 6 per cent per year, so that T_b for strontium in bone would be about 12 yr (4400 days). This is less than the value proposed by Committee II of ICRP: $T_b = 18,000$ days. In general, our results are consistent with LOUPTON's estimate that about one-seventh of the strontium absorbed remains in the body at the end of the first year. If excretion by our subjects had continued at about the rate that we observed during the first several hundred days, then about 16 per cent of the ^{85}Sr absorbed would have been retained at the end of the first year (see Fig. IV.4).

We were perplexed by the occasions when the net counting rate was significantly different from that expected on the basis of previous serial measurements. After excluding all possible operating errors, unexpected results were obtained in sixteen of the forty-five subjects who received ^{85}Sr . Examples of these are shown in Fig. IV.2. The curve for LS-2 is satisfactory, while that for DS-8 demonstrates almost complete disappearance of ^{85}Sr between the Days 62 and 100. Four others behaved in the same fashion, all occurring during the summer months. Aside from the possibility that vigorous physical activity may have been responsible we have no explanation for the occurrence. In several subjects there was an unexplained increase in the net

counting rate as illustrated by the curve for LS-1. It is conceivable that redistribution of ^{85}Sr in the skeleton permitted the detectors to "see" activity with greater efficiency. This could happen if strontium deposited in the vertebrae and ribs was relocated to arms or legs where there is a smaller amount of overlying soft tissue. All subjects were counted in the prone and supine position to compensate for unequal anterior-posterior distribution such as may occur in the trunk region. Obviously such variations complicate any study of long-term retention.

Barium. Because of their cardiotoxicity little is known about the long-term metabolism of barium salts beyond the fact that approximately 70 per cent of the fraction absorbed from the gut goes to bone where the half-life is reported to be 65 days (Table I.1). We fed DS consisting of $\text{BaO} + ^{133}\text{BaO}$ to eight subjects, but only four absorbed a sufficient amount to permit an estimate of f_A . Long-term retention could be followed in three of these for times ranging from 100 to 340 days. Unexpected variations of net counting rate occurred in all three and resembled those seen with ^{85}Sr . The data for the subject who absorbed the most barium ($f_A = 0.15$) are shown in Fig. IV.2. The configuration of the curve resembles that for strontium, retention measured at about 1 yr (340 days).

25 per cent of the amount absorbed. The DS made with ^{133}Ba was the most soluble of the simulants used.

V. CONCLUSIONS

After 2½ years of work and the planned exposure of 102 healthy volunteers to small amounts of internal radiation it is appropriate to ask what we have learned that has relevance for Civil Defense and health physics.

First, we are not in much better shape than when we started with respect to our ability to predict the magnitude of the hazard from internal deposition of radioactivity following ingestion of fallout particles. It appears that local siliceous fallout is not so soluble as it was assumed to be—if our sample was at all typical. The biological availability of radioactivity from such fallout was about one-third of the value usually quoted. This small advantage is offset by the uncertainty of intestinal motility which may vary over quite a wide range. There is also evidence—not too conclusive perhaps—that the intestinal contents of man are much more effective than dilute acid or alkali as a leaching agent for the glassy simulant that we used. We have not studied the reactions responsible for this and cannot say whether enzymes, chelating agents or intestinal microflora are responsible. On the basis of our limited experience it does not seem proper to equate biological availability with solubility or leachability as measured by soak tests using 0.1 normal acid and alkali.

Second, we have demonstrated that it is not necessary to use particulate simulants of fallout to study the metabolism of such critical nuclides as those of strontium, cesium or barium. The metabolic fate of strontium and cesium that gain entrance to the blood is apparently not influenced by the manner or rate at which they get there, and presumably the same is true for barium. This conclusion is not trivial, however, because it was perfectly legitimate to speculate that there might be quantitative or qualitative differences in the fashion in which the body disposes of material injected intravenously, and unknown chemical compounds of the same element absorbed from the gut.

Third, we learned quite a bit about the distribution of such values as the fraction of dose absorbed from the gut and the rate of elimination

of strontium, cesium and barium. This was possible because of the large number of volunteers who were willing to participate in a study that concerned an aspect of Civil Defense. It was also possible because of the comparative ease of measuring long-term retention of γ -emitting nuclides using the whole-body counter. The important finding was a better delineation of biological variability, which is considerable for cesium, and much greater for strontium and barium. The range of variability was greater than we had anticipated.

Fourth, there appears to be little difference between our findings with healthy active volunteers and the results reported by others who studied hospitalized patients whose metabolic state was not greatly disturbed by illness.

Finally, our results may be useful to health physicists by providing additional empirical information about absorption and elimination of strontium, cesium and barium. When our values are compared with those of the ICRP (see Table I.1) there is good agreement for the absorption of cesium: $f_A = 0.89$ vs. $f_1 = 1.0$. Our mean value for f_A of strontium—0.17—is probably significantly lower than the ICRP's $f_1 = 0.30$. We had too few subjects to warrant any conclusion about the absorption of barium except that it varied remarkably.

The biological half-time (T_b) for cesium in our healthy young adults was 91 ± 18 days which is probably not significantly greater than the ICRP value: 70 days. It is difficult to evaluate T_b for strontium since we used the relatively short-lived ^{85}Sr , and have no information about long-term retention (i.e. longer than 1 yr): our longest study was 247 days. We can say with some confidence that about 40 per cent of strontium absorbed from the gut was eliminated during the first week after a single ingestion, and that about one-sixth of the fraction absorbed remained in the body at the end of the first year. This burden which is equivalent to about 3 per cent of the amount ingested (0.16×0.17) is surely available for long-term retention. During the first year after ingestion we can estimate a T_b of about 50 days for short-term turnover for 10 per cent of the amount ingested (0.17×0.60) since 60 per cent of the fraction absorbed remained at 7 days, and about 30 per cent at 50 days. (See Fig. IV.3.) Following LOUITT⁽¹¹⁾

we may assume that strontium remaining after about 1 yr is subject to long-term turnover as bone is replaced at a rate that approximates 6 per cent per year in adults ($T_b = 12$ yr). Using these values in the case of a single ingestion of ^{90}Sr would result in a much smaller estimate of radiation dose to bone than is found when the ICRP values are used: $f_w = 0.21$, and $T_b = 1.8 \times 10^4$ days.*

Barium should behave like strontium with respect to long-term retention, and the fraction ultimately deposited in bone should turn over at a rate that approximates that of bone replacement. The ICRP value for T_b of barium is 65 days, and is quite different from what we found in three satisfactory studies (see Table IV.5). Approximately one-half the fraction absorbed (f_A) was eliminated during the first 50 days, as was the case with strontium. At the end of 1 y the measured retention of barium was 25 per cent of the amount absorbed in one subject, and in another the extrapolated retention was about 10 per cent.

Individual variation in the absorption of strontium and barium was remarkable and we have no explanation for the cause of it. Even more difficult to explain is the unexpected reduction of strontium burdens in five of eighteen

subjects who were studied for longer than 6 months. In each case the drop occurred after a vacation, and may well have been associated with accelerated remodeling of bone provoked by unusual physical activity. This variability in the metabolic behavior of strontium and barium is in striking contrast to that of cesium which was almost completely absorbed from the gut and eliminated at strictly exponential rates by all twelve subjects.

SUMMARY

(1) The behavior of real and simulated fallout following ingestion was studied in 102 volunteers using the whole-body gamma spectrometer.

(2) Ten volunteers ingested samples of typical local fallout. The average biological availability of the radioactivity in this material was 3 per cent. Two of the subjects absorbed almost none, and only four of the ten absorbed more than 3 per cent.

(3) The rate of excretion of insoluble particulate material from the gastrointestinal tract was followed in twenty-seven subjects. On the average about one-half the material was excreted during the first 2 days following ingestion. In all but three of seventeen subjects 99.9+ per cent was gone by the seventh day.

(4) Simulants of fallout labeled with ^{85}Sr , ^{134}Cs or ^{133}Ba were fed to forty-three subjects, and solutions of $^{85}\text{SrCl}_2$ or $^{134}\text{CsCl}$ were fed to twenty-two. The rate of elimination of strontium and cesium was the same whether the tracer was given in solution or whether it was absorbed from the simulant.

(5) On the average, about 17 per cent of the strontium tracer was absorbed from the gut. Of the amount absorbed, about 60 per cent was retained at the end of the first week and about 16 per cent at the end of 1 yr. Carrier strontium enhanced absorption but appeared to decrease retention to some extent. The biological variability of absorption of strontium was large: when $^{85}\text{SrCl}_2$ was fed the fraction absorbed ranged from 0.08 to 0.34.

(6) In twelve subjects the biological half-time for elimination of ^{134}Cs was 91 ± 18 days. When $^{134}\text{CsCl}$ was fed about 90 per cent of the tracer was absorbed.

(7) Using $\text{BaO} + ^{133}\text{BaO}$ as a distant simulant

* Total dose (D_β) to bone after a single ingestion of $100 \mu\text{c}$ of soluble ^{90}Sr :

(1) Using ICRP values for biological and physical constants:

$$f_w = 0.21, T(\text{bone}) = 6400 \text{ days, and using } \Sigma EF(\text{RBE})_n \text{ for } ^{90}\text{Sr}-^{90}\text{Y} \text{ for } E_\beta \text{ in bone} \\ = 5.5 \text{ MeV}$$

$$D_\beta = 73.8 C E_\beta T \text{ rad} \\ = 73.8 \times 0.003 \times 5.5 \times 6400 \\ = 7793 \text{ rad.}$$

(2) Using values suggested by this study:

"Short-term" turnover:

$$f_w = 0.07 \text{ (i.e. 10 per cent of ingested remains presumably in bone after 1 week; and 3 per cent remains after 1 year),}$$

$$T = 50 \text{ days, and } E_\beta = 5.5 \text{ MeV}$$

$$D_\beta^1 = 73.8 \times 0.001 \times 5.5 \times 50 \\ = 20 \text{ rad.}$$

"Long-term" turnover:

$$f_w = 0.03, T_b = 4400 \text{ days}$$

$$T = 3000 \text{ days; } E_\beta = 5.5 \text{ MeV}$$

$$D_\beta^2 = 73.8 \times 0.0004 \times 5.5 \times 3000 \\ = 487 \text{ rad.}$$

$$D_\beta = D_\beta^1 + D_\beta^2 = 507 \text{ rad.}$$

DS) average absorption was 6 per cent in eight subjects, with a range of 1–15 per cent. Elimination of barium by one subject was slower than for strontium: 25 per cent of the amount absorbed was retained at the end of 1 yr.

(8) There was no correlation between the biological availability of the simulants and leachability or solubility as measured by soak tests in 0.1 N HCl and 0.1 N NaOH.

Acknowledgements—The authors are indebted to Dr. CAROL M. NEWTON for assistance in the early phase of this study. They are especially grateful to the 102 volunteers who hoped that they were making a contribution to Civil Defense.
