#### Abstract

The USGS Place Based Studies Program for San Francisco Bay investigates this sensitive estuarine system to aid in resource management. As part of the inter-disciplinary research program, the USGS collected side-scan sonar data and bed-sediment samples from north San Francisco Bay to characterize bed-sediment texture and investigate temporal trends in sedimentation. The study area is located in central California and consists of Suisun Bay, and Grizzly and Honker Bays, sub-embayments of Suisun Bay. During the study (1998-2002), the USGS collected three side-scan sonar data sets and approximately 300 sediment samples. The side-scan data revealed predominantly fine-grained material on the bayfloor. We also mapped five different bottom types from the data set, categorized as featureless, furrows, sand waves, machine-made, and miscellaneous. We performed detailed grain-size and statistical analyses on the sediment samples. Overall, we found that grain size ranged from clay to fine sand, with the coarsest material in the channels and finer material located in the shallow bays. Grain-size analyses revealed high spatial variability in size distributions in the channel areas. In contrast, the shallow regions exhibited low spatial variability and consistent sediment size over time.

Figure 1: Location map

## Introduction

The San Francisco Bay estuary begins at the confluence of the Sacramento and San Joaquin Rivers in central California. Since the discovery of gold in 1848, the region has undergone immense environmental changes. Hydraulic mining activity during the late 1800's in the Sierra Nevada resulted in the influx of large quantities of sediment to the San Francisco Bay estuary (Gilbert, 1917; Cappiella et al., 1999). At the same time, increased development has resulted in the loss of wetlands, re-routing of rivers, and species decline. The USGS Place Based Studies Program is an inter-disciplinary program aimed at understanding the San Francisco Bay estuary
system, its response to modern stresses, and disseminating information to aid in resource management of the area.

As part of the San Francisco Place Based Studies Program, the USGS began research in northern San Francisco Bay to characterize bed-sediment texture and investigate temporal trends in sedimentation. The study area comprises approximately $170 \mathrm{~km}^{2}$ and consists of Suisun Bay, and Grizzly and Honker Bays, sub-embayments of Suisun Bay (Fig. 1). At present, the region is characterized by three channels. The primary navigation channel is situated on the south side of Honker Bay into Suisun Bay, where it passes south of Ryer Island. A smaller channel runs between Roe Island and Ryer Island. The third channel flows through Suisun Cutoff, north of Ryer Island, on the south side of Grizzly Bay, and through the Reserve Fleet Channel on the western side of Suisun Bay. All three channels join at Carquinez Strait where they continue through the southern section of San Pablo Bay and into the Central Bay. The channels and shallows range in depth from 10 to 22 m and 1 to 2 m , respectively.

During the years 1998 through 2002, the USGS collected bed-sediment samples, and performed three side-scan sonar surveys of the region. We completed grain-size and statistical analyses on the sediment samples, which were compiled in a spreadsheet and are included with this report as Tables 2 and 3. The side-scan sonar data (Plate 1) from one survey was digitally mosaiced and interpreted to reveal bed morphology and composition.

## Methods

The following section describes sample collection, sediment grain-size analyses, and side-scan sonar data collection.

## Sediment Sample Collection

Sediment sampling took place between December 1998 and January 2002 using two USGS research vessels, the RV David Johnston and the RV Polaris. Table 1 summarizes the details regarding each cruise such as the research vessel, cruise ID, cruise dates, the number of samples collected, and whether side-scan sonar data was collected. Additional information on these cruises can be found at the link provided in Table 1.

The goal of the sampling scheme with the RV Johnston was to collect samples before and after the rainy season to investigate possible seasonal changes in bed texture (Table 1). The sample locations using this vessel are displayed on Figures 2-5 with symbols colored to represent percent sand-sized material. Percent sand is emphasized in this report as a means of characterizing the bimodal distribution of grain sizes in the samples. The sediment sampling locations ranged from Montezuma and Suisun Sloughs to the north, Honker Bay to the east, and Carquinez Strait to the west. Sampling was largely concentrated in the channel area known as Garnet Sill (Fig. 1; Plate 1) due to its location as an important area of estuarine mixing adjacent to the large shallow-water habitat of Grizzly Bay (Schoellhamer, 2001). Sampling depths ranged from 1.17 m to 15.63 m .

The RV Polaris was used for seven sampling cruises from 2000 to 2002 as indicated on Table 1. Unlike the Johnston cruises, samples were collected at 12 specific sites (Fig. 6) at variable intervals throughout the year. These locations are part of a network of long-term monitoring sites used by the USGS (see http://sfbay.wr.usgs.gov/access/wqdata/ for more information). Sampling depths ranged from 1.5 m at locations 415,416 , and 417 , to 17.4 m at location 8.1 (Fig. 6). The shallow regions in the sloughs and Grizzly Bay were sampled using a smaller boat transported aboard the RV Polaris.

We used two types of equipment for the sampling: a Van Veen grab sampler, and box cores. The grab sampler has a clam-like scoop, and can penetrate about 20 cm deep. Sampling involved careful selection of the surface layer of sediment (top $\sim 1 \mathrm{~cm}$ ) into two sample bags, one for
archive and one for analysis. The majority of the RV Johnston samples and all of the RV Polaris samples were collected using this instrument. A few samples on the RV Johnston cruise were collected by scraping the fine surface sediment from the top of a box core. Occasionally, samples were taken from various intervals below the surface in the grab or core. The specific equipment and interval used for each sample is indicated on Tables 2 and 3. After collection, samples were stored in a refrigerator on board the boat, and then transferred to a refrigerator in Menlo Park where they were stored at $3.8^{\circ} \mathrm{C}$.

## Sediment Grain-Size Analysis

Grain-size analysis typically lasted about one week for a batch of 30 samples. All instrumentation used for the analysis is located on the USGS Menlo Park campus. The following sections describe the various instruments used and a detailed account of the laboratory procedures.

## Differing Grain-Size-Analysis Methodologies

Comparisons between the RV Johnston datasets are hampered by the changing methodologies used for the grain-size analysis. We used three different methods of analysis on the RV Johnston samples during the course of the project. The oldest samples of the data set (J-5-98-SF) were processed using the Rapid Sediment Analyzer (RSA) for the intermediates, and the Micromeritics 5100 Sedigraph $^{1}$ for the fine material. 10 samples from the J-2-99-SF cruise were analyzed using the RSA for the intermediates, and the Coulter LS100Q ${ }^{1}$ laser particle-size analyzer for the fines. The remaining RV Johnston samples and all of the RV Polaris samples were processed utilizing only the laser particle-size analyzer for both size fractions. It is important to note that the RV Polaris samples were processed by the same individual and used a consistent analysis method, facilitating comparisons between samples throughout the study period. The techniques used to analyze the samples from the RV Johnston and the RV Polaris are indicated on Tables 2 and 3, respectively.

The changing methodologies were due to the limitations of the Sedigraph in processing the finest fraction ( $<0.0005 \mathrm{~mm}$ ) of material. As a result, the data for the J-5-98-SF cruise show an increase in this size fraction as seen on Figures 7A and B. The laser particle-size analyzer was ultimately chosen as the best laboratory technique because of its ability to analyze a large range of grain sizes ( 0.0003 mm to 1.0 mm , 11.5 phi to 0 phi,), resulting in the use of only one instrument.

In order to facilitate comparisons between the samples, we omitted the coarsest material ( $>1 \mathrm{~mm}$ ) from the RV Johnston samples for the computer analysis. We made this change for two reasons: 1) this size category was processed using different methods at various times during the study, and therefore not quantitatively comparable; and 2) we found that in nearly every case the coarsest material was predominately composed of shells and not elastic sediment. By omitting this category from the analysis, we aided comparisons between the data sets, and reduced skewing of the statistics by non-bed-sediment material. However, we chose not to omit this size fraction from the RV Polaris analyses due to the consistent methodology used in processing the samples.

[^0]
## Removal of Organics (all samples)

30-80 g of a homogenized sample was placed in a beaker with 400 ml of deionized (DI) water and $20-30 \mathrm{ml}$ of $30 \%$ hydrogen peroxide $\left(\mathrm{H}_{2} \mathrm{O}_{2}\right)$ to oxidize and remove organic matter. The solution was covered over night for sufficient oxidation to occur, and was then boiled for 4-6 hours to evaporate the remaining $\mathrm{H}_{2} \mathrm{O}_{2}$.

## Centrifuging (all samples)

After oxidation, each sample was poured into a $250-\mathrm{ml}$ bottle(s) and centrifuged at 1700 rpm for 30 minutes. The salts and water were decanted off the top, and the bottle was refilled with DI. The sample was then centrifuged for another 60 minutes, and decanted one more time.

## Sieving and Determining Coarse and Intermediate Weights

All RV Johnston samples (J-5-98-SF, J-2-99-SF, J-3-99-SF, and J-1-00-SF)
After removing the salts, each sample was wet sieved into a 1-L graduated cylinder using 2-mm and $0.063-\mathrm{mm}$ sieves. The coarse and intermediate material caught in the $2-\mathrm{mm}$ and $0.063-\mathrm{mm}$ sieves, respectively, was then transferred into pre-weighed crucibles, dried at $70^{\circ} \mathrm{C}$, and weighed. The coarse and intermediate weights were determined by subtracting the weight of the crucible.

## All Polaris samples

After removing the salts, each sample was wet sieved into a pre-weighed beaker using 2-mm, 1.4mm , and $1-\mathrm{mm}$ sieves. The material caught in the sieves was transferred to pre-weighed crucibles, dried at $70^{\circ} \mathrm{C}$, and weighed. The weight of the material was determined by subtracting the weight of the crucible.

## Determining the Weight of the Fines

All RV Johnston samples (J-5-98-SF, J-2-99-SF, J-3-99-SF, and J-1-00-SF)
In order to determine the weight of the fine fraction in the sample, a standard pipette analysis based on settling velocity (Stokes' Law) was used (Carver, 1971).

## All Polaris samples

The weight of the material $<1 \mathrm{~mm}$ was determined after the size-distribution analysis was finished by drying the entire sample at $70^{\circ} \mathrm{C}$, and subtracting the weight of the beaker and the dispersant.

## Size Distribution for the Intermediates (intermediates and fines for the RV Polaris samples)

## All J-5-98-SF samples and 10, J-2-99-SF samples

The intermediate weight percents were determined for every half-phi interval from 0.063 mm to 1.0 mm ( 4.0 phi to 0 phi) using the Rapid Sediment Analyzer (RSA) settling tubes. Material was released into a 2 -m water column where it settled onto a weighing plate. A graph of cumulative weight versus time was recorded on a chart recorder, from which the size distribution could be extracted (Maher, et al., 1991).

The intermediate weight percents were determined using the large volume module laser particlesize analyzer. This instrument counts particles from 0.0003 mm to 1.0 mm ( 11.5 phi to 0 phi) by using light-scattering theory and lasers to determine the particle-size distribution of a sample (http://walrus.wr.usgs.gov/infobank/programs/html/facilities/mp/15.3/bldg15_m3009a.html). Each sample was agitated for 2 minutes, and then a representative sample was taken using a pipette, and added to the particle-size analyzer. The data were then saved to a computer, and printed according to cumulative weight percent every half-phi interval.

## All Polaris samples

5 ml of dispersant was added to the material $<1 \mathrm{~mm}$ in the pre-weighed beaker. The mixture was then agitated for 1-2 minutes, and sat overnight. 5 ml of dispersant was then added to three preweighed aluminum tins, dried, weighed, and averaged. The intermediate and fine weight percents of the material $<1 \mathrm{~mm}$ were determined using the large volume module laser particle-size analyzer. Each sample was mixed for 2 minutes, and then a representative sample was taken using a pipette, and added to the particle-size analyzer. After the analysis was completed, the sample was flushed out of the particle-size analyzer into pre-weighed beakers, dried at $70^{\circ} \mathrm{C}$, and weighed. The remaining sample not analyzed was also dried and weighed. The combined weights minus the averaged weight of the dispersant yielded a total weight of the material $<1 \mathrm{~mm}$ as described above.

## Size Distribution for the Fines

## All J-5-98-SF samples

5 ml of dispersant was added to the fine fraction to separate clay-sized particles and inhibit flocculation. The mixture was then agitated for 1-2 minutes, and was allowed to sit overnight. 5 ml of dispersant was also added to three pre-weighed aluminum tins, dried, weighed, and averaged. Individual weight percents for material $<0.063 \mathrm{~mm}$ were calculated using the Sedigraph. This instrument employs x-ray-attenuation technology to determine the particle-size distribution of a sample
(http://walrus.wr.usgs.gov/infobank/programs/html/facilities/mp/15.3/bldg15_m3009a.html). Individual weight percents were recorded every half-phi interval from 0.0005 mm to 0.063 mm (11.0 phi to 4.0 phi).

Remaining J-2-99-SF samples, J-3-99-SF, and J-1-00-SF samples
5 ml of dispersant was added to the fine fraction to separate clay-sized particles and inhibit flocculation. The mixture was then agitated for 1-2 minutes, and was allowed to sit overnight. 5 ml of dispersant was also added to three pre-weighed aluminum tins, dried, weighed, and averaged. Weight percents for material $<0.063 \mathrm{~mm}$ were determined using the small volume module laser particle-size analyzer. Each sample was mixed thoroughly, and then a representative sample was taken using a pipette, and added to the particle-size analyzer. The data were then saved to a computer and printed according to cumulative weight percent every half-phi interval.

## Computer Analysis

SDSZ (McHendrie, 1989), a USGS custom-designed grain-size analysis computer program was used to extract the statistics published in this report. We processed weight and size distribution data acquired from the RSA, Sedigraph, and particle-size analyzer with SDSZ. The output data were then organized into a table containing median grain size, moment statistics, percent gravel, sand, silt, clay, and mud (Tables 2 and 3).

## Side-Scan Sonar Collection

We collected side-scan sonar data on three cruises (J-5-98-SF, J-2-99-SF, and J-3-99-SF) in the Suisun Bay study area (including the Grizzly and Honker Bay sub-embayments). Our rationale in acquiring side-scan sonar data was to complement the textural data collected to test the hypothesis that riverine-supplied sediment and seasonal changes might result in changes in the bed morphology and composition (texture). Our purpose was therefore to collect sufficient sonar data over the study area to assess changes in bed morphology and composition. We were limited, though, by equipment availability, data-acquisition malfunctions, and post-processing timing. Due to time constraints and staffing changes we were limited to analysis of the J-5-98-SF data only.

A Klein $2000^{1}$ side-scan sonar system was used on the J-5-98-SF and J-3-99-SF surveys, whereas a Klein $595^{1}$ system was used on J-2-99-SF. We collected 100 kHz sonar data on all three surveys using a swath width of 200 m ( 100 m on each side of the ship track). Navigation data on all surveys utilized differential global positioning systems (DGPS); navigation data were integrated with sonar data and both were stored digitally on optical disks for archiving. 200 kHz bathymetry and 3.5 kHz sub-bottom data were simultaneously collected with the side-scan sonar data. J-5-98-SF sonar data were collected in the "non-mapping" mode as we intended to post-process the data and mosaic all survey tracks. However, due to time constraints, J-2-99-SF and J-3-99-SF sonar data were collected in the "scale-corrected mapping" mode such that hard-copy sonar profiles were spatially corrected both in the along-track and across-track aspects by integrating both boat speed and DGPS. The sonar towfish on every cruise was towed immediately behind the RV Johnston such that the distance between the DGPS antenna and the towfish was negligible. Horizontal resolution of all sonar data is approximately 1-2 m. Theoretical vertical resolution of the 100 kHz sonar data is approximately 10 cm such that bed features smaller than 10 cm cannot be resolved in detail.

## Results

## Grain-Size Analysis

## RV Johnston samples

The grain-size analyses for the RV Johnston samples yielded median values ranging from 0.0015 mm to 0.46 mm ( 9.3 phi to 1.1 phi), with an average median grain size of 0.032 mm ( 4.9 phi). To facilitate comparisons among samples from regions with similar morphology (Plate 1), grain-size distribution graphs from the Garnet Sill and Grizzly Bay regions are shown on Figure 7. We delineated the Garnet Sill and Grizzly Bay samples based on the side-scan sonar data. The sample ID, number of samples in each category, and the average percent sand-sized material are indicated on each graph. Figure 7 does not include all sample data collected on the RV Johnston

[^1]cruises due to a small number of samples collected outside the Garnet Sill and Grizzly Bay regions. Samples collected in the Garnet Sill region (Figs. 7A, C, E, and G), often display a bimodal distribution. These fine sand and silt modes often are the result of distinct, thin ( $<0.5-1$ cm ), stratigraphic layers, seen in the grab or box core sampler. In any given sample, the relative abundance of each mode reflects primarily the quantity of each layer subsampled by the operator. This fine-scale stratigraphic heterogeneity is typical of channel samples throughout the study area, and is consistent with the spatial heterogeneity of return strength seen in the side-scan sonar data for Garnet Sill (Plate 1).

The samples collected with the RV Johnston in the shallower regions of Grizzly Bay are dominated by silt and clay as seen on Figures 7B, D, F, and H. A few samples from the channel area on the west side of Grizzly Bay near the mouth of Suisun and Montezuma Sloughs have a fine sand mode (Figs. 7B, D, F, and H, samples 18, 54, 62, 103, 95, 199, 209). As previously mentioned in this report, the emphasis on fine material associated with using the Sedigraph instrument is seen on Figures 7A and 7B as an increase in material at the fine end of the distribution.

## RV Polaris samples

The RV Polaris data show grain-size trends at 12 specific locations from August 2000 to January 2002 (Table 1). The results indicate an average median grain size of 0.042 mm ( 4.6 phi) ranging from 0.006 mm to 0.38 mm ( 7.4 phi to 1.4 phi). The grain-size distributions for all 12 sites are displayed on Figures 8 and 9. Samples collected in the channel regions (Figs. 8A, B, C, D, E, F and 9A, and E) display a similar bimodal distribution of fine sand and silt to the RV Johnston Garnet Sill samples, with generally consistent distributions during the study period. Location 411.1 (Fig. 9A), on the western side of Garnet Sill exhibits the greatest variability in grain-size distribution, with median size ranging from 0.011 mm to 0.022 mm ( 6.6 phi to 5.5 phi). This range likely reflects stratigraphic, spatial, and possibly temporal variability of bed-sediment at this sampling site, similar to the other Garnet Sill samples (Fig. 7). This particular location is relatively fine compared to Garnet Sill as a whole.

The samples collected in the shallow areas during the RV Polaris cruises fall into three locations, Montezuma Slough, Grizzly Bay, and Honker Bay. The Montezuma Slough samples (site 415, Fig. 9B) contain the coarsest sediment of those collected in the shallow regions of the study area, and resemble a fine channel sample. The graph on Figure 9B exhibits a dominant mud mode with a prominent fine-sand mode, which is typical of the slough samples from the RV Johnston cruises (Table 2). The grain size distribution of all six samples collected at this site exhibit remarkable similarity. The data results for the samples collected in Grizzly (site 416 and 417, Fig. 9C and D) and Honker Bays (site 433, Fig. 9F) are extremely fine grained with almost no sand present in the samples. These data sets are also noteworthy in their consistency in grain size over time.

## Side-Scan Sonar Analysis

J-5-98-SF sonar data were interpreted using bottom morphology (side-scan and fathometer) and relative strength of backscatter (a measure of bottom roughness and type of bed material), these parameters being key indicators of bed morphology and composition. In general, coarse-grained bed-sediments yield higher backscatter (light tones on Plate 1), and fine-grained material yields weak backscatter (dark tones on Plate 1). One can immediately deduce from the predominance of darker tonal patterns on the mosaic (Plate 1) that much of the bayfloor of the study area surveyed is composed of fine-grained material (very fine sand and finer) and is "relatively smooth"
(lacking significant bed roughness or relief). This agrees with conclusions derived from the textural data.

5 bottom types can be identified in the J-5-98-SF sonar data.

1) Featureless- where there are no discernible bed features and the tonal pattern is fairly constant across the profile for the specific area mapped. A derivative of this bottom type is the tonal pattern that occurs over Garnet Sill (elaborated on below). Featureless bottom occurs throughout the study area but predominates in the shallowest areas where the texture is typically very fine grained (mud), and the floor is relatively flat to gently sloping. It also occurs in localized areas admixed with other bottom types such as sand waves or furrows. Due to the resolution of the side-scan sonar systems used ( 10 cm ), there could be smaller bed features present but that might appear as "flat" bottom on the sonar profile. In the Garnet Sill area (Fig. 1) the bottom is relatively flat to gently sloping and there is little vertical relief, as determined from fathometer profiles across the area. However, Plate 1 reveals that on the sonar mosaic a distinct demarcation exists between a darker tonal area (on the north side) and a lighter tonal area (on south side). The demarcation roughly coincides with the 4 m isobath. Since the tonal pattern is not due to bottom relief or roughness, we think that it is caused by a compositional difference in the bed-sediments. Figure 2 depicts surface sample locations and also the percent sand of bed sediment over the Garnet Sill area during the period when the sonar data (J-5-98-SF) was acquired. Sediment samples north of the 4 m isobath are predominately mud whereas samples south of the 4 m isobath are predominately sandy sediment. This textural difference in the bed sediment is manifest in the sonar profile by the tonal contrast on each side of the 4 m isobath (dark tone is finer muddier sediment, light tone is coarser sandier sediment).
2) Furrows- a sedimentary bed feature (bedform) that results from the molding of the bed by physical processes (largely tidal flow). Furrows consist of a series of elongate and parallel grooves separated by intervening ridges. They form parallel to the dominant flow, which formed and subsequently maintains them. These bed features were only found on the western side of the Reserve Fleet Channel in westernmost Suisun Bay (Fig. 1; Plate 1). Many vessels of the Reserve Fleet rest at anchor over furrows. Furrows can be traced discontinuously from just east of Benicia northeast to Garnet Sill. To the south they terminate against sand waves and/or bedrock adjacent to the Benicia-Martinez Bridge/SP Railroad Bridge, and to the north they terminate against the western edge of the tonal area on Garnet Sill (Plate 1). Sonar and fathometer profiles reveal that furrows are less than 1 m in height and less than 2-5 m in wavelength and occur mostly in less than 6 m water depth. They exhibit tuning forks, although the forks do not open preferentially in either flood or ebb directions. Sediment samples (surface and box cores) in the furrow field show that they are dominantly cohesive mud. Furrows were present in the same location on all threesonar surveys; we could not document whether individual furrows had migrated.
3) Sand waves- a sedimentary bed feature (bedform) that results from the molding of the bed by physical processes, such as tidal flow. We mapped two types of sand waves based on their vertical relief (from sonar and fathometer profiles): $<1 \mathrm{~m}$ and 1-2 m . Wavelengths ranged from 2 m to 10 m . Sand waves in the 1 m and smaller category are ubiquitous and were observed in all of the tidal channels. The 1-2 m size was only observed under the Benicia-Martinez Bridge and in the navigation channels in Suisun Bay. The orientation of sand waves was not recorded, nor was their ebb or flood dominance---both ebb and flood oriented sand waves were observed. Areas where no sand waves were observed include the western margin of the Reserve Fleet Channel, Garnet Sill, Grizzly Bay, and Honker Bay.
4) Machine-made- bottom features that most likely result from mechanical alteration of the bayfloor. These include but are not limited to anchor drag marks, trawl marks, keel marks, and
bridges and/or pipeline supports. Anchor, trawl, and keel marks can commonly be differentiated from natural features in that they usually cross each other, often several times. They also commonly occur adjacent to areas such as docks, navigation channels, and anchored vessels. Pipelines, bridges, bridge support structures, and docks coincide exactly with analogous features on the navigational chart of Suisun Bay (N.O.S. sheet \# 18656, 1992 ed., scale 1:40,000). We also observed semi-circular features adjacent to the former Concord Naval Weapons Station (Port Chicago) dock facilities that appear to be the result of dredging.
5) Miscellaneous- include small localized areas of the bayfloor where the side-scan sonar signal was "acoustically blanked out". The features actually occur in the water column above the bed and prevent a return signal from the bayfloor by totally dampening the outgoing sonar signal. These occurred only in the southeastern end of Suisun Cutoff adjacent to the southern tip of Ryer Island in waters up to 22 m deep. Their location coincides with deep but localized depressions that are irregular in shape. The sonar profile appears white or blank with no tonal contrast present.

## Spatial and Temporal Trends

One of the goals of this study was to investigate possible temporal trends in bed grain size and morphology associated with river flood events or seasonal winnowing of fine sediment, as seen in some fluvial systems (e.g. Rubin and Topping, 2001). As mentioned above, the shallow-water samples from throughout the study area show remarkable consistency in grain size despite sampling during all seasons (Figs. 7 and 9). Conversely, considerable variability in grain size exists in the channel areas. However, the fine-scale stratigraphic and spatial heterogeneity seen in many of the samples from these areas (Figs. 7-9) hampers the utility of this data set as a record of temporal trends in bed grain size. One way to conduct a more effective investigation of temporal trends would be to sample with greater spatial and temporal density in a few well-defined locations. Another possible future research direction would be to increase sampling density through the use of underwater microscope and digital image analysis technology (e.g. Chezar, 2001; Rubin, D.M., 2004, in press).

## Conclusion

Our research on bed morphology and texture in Suisun, Grizzly, and Honker Bays was accomplished by collecting and analyzing side-scan sonar data and bed-sediment samples during 1998-2002. The results of the side-scan sonar analysis reflected fairly uniform and fine-grained bed composition in the study area. Five different bottom types were also identified as part of the analysis, which included featureless, furrows, sand waves, machine-made, and miscellaneous bottom morphologies. Bed-sediment samples from Suisun, Grizzly and Honker Bays show median grain sizes ranging from fine silt to fine sand. Samples from channel regions are generally bimodal with distinct fine sand and silt units, reflecting the high degree of stratigraphic and spatial heterogeneity seen in these areas. Samples from the shallow regions of Grizzly and Honker Bays are silt and clay with little spatial or temporal variability.

## Acknowledgements

This research was funded by the USGS Place Based Studies Program. We thank: Cindy Brown, Paul Carlson, Robin Dornfest, Wilson Lee, Francis Parchaso, Byron Richards, Cathy Ruhl, Dave Schoellhamer, and Gordon Smith for help with field operations; Simon Barber, Danielle Giroux, and Mike Torresan for help with laboratory sample analysis; Bruce Jaffe for project guidance. This report benefited from reviews by Bruce Jaffe and Jessica Lacy.

## Table Explanation:

Cruise: Name of cruise.
Sample ID: sfc= collected at surface of box core or grab sample, mid= collected in the middle of box core or grab sample, btm= collected at the bottom of box core or grab sample, $\mathrm{m} / \mathrm{b}=$ collected in the mid/bottom range of box core or grab sample.
Instrument: VV=Van Veen grab sampler, BC=box core sample.
Latitude/Longitude: Displayed as decimal degrees.
Date/Time: year/Julian Day/time
Method: RSA/SG=Rapid Sediment Analyzer (intermediates) and Sedigraph (fines), RSA/CC=Rapid Sediment Analyzer (intermediates) and particle-size analyzer (fines), CC= particle-size analyzer.

Table 3: Grain-size distributions for 7 RV Polaris cruises
Note: All statistics in phi units

| Cruise | $\begin{array}{\|c\|} \hline \text { Sample } \\ \text { ID } \end{array}$ | $\begin{array}{\|c\|} \hline \text { Station } \\ \text { ID } \end{array}$ | Instrument | Latitude | Longitude | Date/Time | Method | $\%$ <br> Gravel <br> $>2$ <br> mm | \% <br> Sand <br> $.062-$ <br> 2 mm | $\%$ Silt <br> $.004-$ <br> .062 <br> mm | $\begin{array}{\|c\|} \hline \% \\ \text { Clay } \\ <.004 \\ \mathrm{~mm} \\ \hline \end{array}$ | $\%$ <br> Mud <br> $<.062$ <br> mm | 1 st <br> moment <br> (mean) | $2^{\text {nd }}$ moment (variance) | Std. deviation | 3rd moment (skewness) | 4th <br> moment <br> (kurtosis) | Median |

Table Explanation:
Cruise: Name of cruise.
Sample ID: sfc= collected at surface of box core or grab sample, mid= collected in the middle of box core or grab sample, btm=
collected at the bottom of box core or grab sample, $\mathrm{m} / \mathrm{b}=$ collected in the mid/bottom range of box core or grab sample.
Station ID: (Only for RV Polaris samples) Indicates the station ID for each sample.
Instrument: VV=Van Veen grab sampler, BC=box core sample.
Latitude/Longitude: Displayed as decimal degrees.
Date/Time: year/Julian Day/time
Method: RSA/SG=Rapid Sediment Analyzer (intermediates) and Sedigraph (fines), RSA/CC=Rapid Sediment Analyzer (intermediates) and particle-size analyzer (fines), CC= particle-size analyzer.
