# **Key words**

asteroid; meteorite; physical properties; magnetic susceptibility; induced magnetization, remote sensing; density; solar wind, IMF.

### **Abstract**

Based on reflectance spectroscopy and chemical / mineralogical remote sensing methods it is generally assumed that asteroids are parent bodies for most meteorites reaching the Earth. However, more detailed observations indicate that differences exist in composition between asteroids and meteorites resulting in difficulties when searching for meteorite – asteroid match.

We show that among other physical parameters the magnetic susceptibility of an asteroid can be determined remotely from the magnetic induction by solar wind using an orbiting spacecraft or directly using the AC coil on the lander or measured on sample return in the laboratory. The shape corrected value of the true magnetic susceptibility of an asteroid can be compared to those of meteorites in the existing database allowing closer match between asteroids and meteorites. The database of physical properties contains over 700 samples and was recently enlarged with measurements of meteorites in European museums using mobile laboratory facility.

### Introduction

The objective of asteroid and comet investigation is the characterization and classification of these bodies using remote data acquisition systems. It is generally assumed that asteroids are parent bodies for most

meteorites reaching the Earth (Wasson and Wetherill, 1979; Feirberg et al, 1982). The reflectance spectroscopy of asteroids proved to be powerful tool in characterization of the asteroid composition and classification. The extended taxonomy (Tholen, 1984; modified by Bus and Binzel, 2002) defines total of 26 classes of the asteroid reflectance spectra. Three major groupings (S, C, and X complexes) show spectral similarities to the major meteorite groups. The composition of the S-class asteroids is similar to the silicate-rich ordinary chondrite group, the C-class contains asteroids which are rich in carbonaceous material similar to that of carbonaceous chondrite group and X-class contains various asteroid types mostly rich in metallic component. However, when analyzing the whole spectral curve the exact match between asteroids and meteorites is not found due to differences in their spectral patterns.

Thus, other remote sensing methods are applied during asteroid reconnaissance in order to improve the knowledge of the asteroid chemical and mineralogical composition and to determine possible meteorite equivalents to the asteroid compositions. We show that the physical properties of asteroids and meteorites – mainly the magnetic susceptibility and density – can be applied along with the chemical and mineralogical methods in building the link between meteorites and asteroids.

### **Instruments and methods**

The meteorites represent valuable rare material and it is difficult to bring meteorites directly to the laboratory for scientific studies. Thus, the mobile laboratory facility including portable instrumentation was assembled at Division of Geophysics, University of Helsinki in order to perform the research tour over the museums and collections in Europe and to measure the physical properties of meteorites using harmless, non-destructive methods.

During the meteorite research tour the measurements of bulk physical parameters (magnetic susceptibility, bulk and grain density and porosity) of meteorites were performed. Due to the rare nature of meteorites only harmless, non-destructive methods were applied.

The Hämäläinen TH-1 portable susceptibility meter with large (12 cm) coil was used for susceptibility measurements of bulk samples and was cross-calibrated with the laboratory RISTO 5 and Agico KLY-3 susceptibility meters.

In order to determine the meteorite bulk and grain density as well as porosity the bulk and grain volume and mass must be measured. For bulk volume measurements the chemically inert tiny glass beads (20 –  $50 \mu m$ ) were used to replace liquids used in traditional Archimedean method. The precision of the glass beads method is  $\pm 0.1 \text{ cm}^3$ . The mass was determined using digital OHAUS balances. The balances were always calibrated prior the measurements using mass standards.

The grain volume was measured by Notari portable air pycnometer working at low pressures. The advantage of this instrument is that it does not require any supply gas and thus is easy to transport. The precision of the pycnometer is  $\pm 0.1$  cm<sup>3</sup>.

The instruments can be easily fitted in a small van building a mobile meteorite laboratory (Kohout *et al.*, 2006). This approach enables to perform the meteorite physical properties measurements using non-destructive methods directly in the meteorite collections under the supervision of the curator.

Figs. 1 and 2 compare the data obtained in the museums using mobile meteorite laboratory (colored symbols) with the older data obtained using fixed laboratory instrumentation (grey symbols). The good agreement between those two data sets proves a good cross-calibration between the portable and laboratory instrumentations.

# Magnetic susceptibility of stony meteorites

Magnetic susceptibility of various meteorites has been systematically studied by Kukkonen and Pesonen, 1983; Terho *et al.*, 1993a, 1993b; Rochette *et al.*, 2001, 2003, 2008; Kohout *et al.*; 2006. The results of these studies indicate that the magnetic susceptibility of various meteorite clans and groups occupy characteristic values with quite uniform distribution (Fig. 1). According to those studies the lowest susceptibility is occupied by SNC (10-100 10<sup>-8</sup> m³/kg) and HED (10-1000 10<sup>-8</sup> m³/kg) achondrites. Aubrites have also low susceptibility values (400-3000 10<sup>-8</sup> m³/kg). Chondrite clan has higher susceptibilities in range of 4000-80000 10<sup>-8</sup> m³/kg (with exception of R-chondrites occupying range of 100-160 10<sup>-8</sup> m³/kg) and stony-irons and irons occupy the highest susceptibility range (100000-2000000 10<sup>-8</sup> m³/kg). However, it is difficult to measure the true magnetic susceptibility of stony-irons and irons due to the shape effect (see section "The role of shape and demagnetization factor") and thus the values contain high level of uncertainty.

The iron content of undifferentiated meteorites is both within the silicates and in the form of fine magnetic grains. Magnetic properties of ordinary chondrite clan (Wasilewski *et al.*, 2002) are mostly related to Fe-Ni compounds, namely  $\alpha$ -kamacite (<7% Ni),  $\gamma$ -taenite (>7% Ni), and  $\gamma$ "-tetrataenite (43-52% Ni) capable of carrying remanent magnetization (Morden and Collinson, 1992; Wasilewski, 1988). The susceptibility of the ordinary chondrites (Fig. 2) is directly related to the amount of metal (FeNi) fraction in non-oxidized form. The lowest susceptibility values occupy the LL chondrite group with range of approximately 300-4000  $10^{-8}$  m³/kg followed by L chondrite group (4000-14000  $10^{-8}$  m³/kg) and H chondrite group (14000-46000  $10^{-8}$  m³/kg). The susceptibility of enstatite chondrite clan falls mostly in range of 46000-80000  $10^{-8}$  m³/kg. Urelites occupy similar susceptibility range (6000-15000  $10^{-8}$  m³/kg) as L type chondrites.

The magneto-mineralogy of the carbonaceous chondrite clan (Rochette *et al.*, 2008) is more complicated containing not only the FeNi, but also oxides, sulphides and carbides. The CM, CV and C2 groups occupy roughly the range of 400-4000 10<sup>-8</sup> m³/kg while the CO3, CK and CI groups fall mostly in the range of 2500-6300 10<sup>-8</sup> m³/kg. The C3-4 groups are characterized by susceptibilities in range of 3100-10000 10<sup>-8</sup> m³/kg. The CR group has values around 10000 10<sup>-8</sup> m³/kg. The highest susceptibility values among carbonaceous chondrites (comparable to those of enstatite chondrite clan) occupy CH group with range of 16000-63000 10<sup>-8</sup> m³/kg. The magnetic susceptibilities of various carbonaceous chondrite groups overlap and are similar to those of ordinary chondrites. However, comparing to ordinary chondrites, the carbonaceous chondrites have in general lower bulk and grain densities (Consolmagno and Britt, 1998; Britt and Consolmagno, 2003; Wilkinson *et al.*, 2003).

# The Finnish database of physical properties of meteorites

The research work of Kukkonen and Pesonen, 1983; Terho *et al.*, 1993a, 1993b and Kohout *et al.*, 2006 has been has been merged in a form of database counting measurements of more than 700 individual meteorite samples from European meteorite collections and is continuously expanded. The database contains measurements of physical parameters including bulk (volume normalized) and mass susceptibility, bulk and grain density, porosity, NRM (Natural Remanent Magnetization), Q-value (Königsberger ratio), various hysteresis parameters and magnetic paleointensity estimates.

In table 1 we present new unpublished mass normalized as well as volume normalized shape corrected magnetic susceptibility values, bulk and grain densities and porosities of meteorite samples obtained using the mobile laboratory (colored symbols in Figs. 1 and 2).

## The role of the shape and demagnetization factor

The magnetic susceptibility  $\kappa$  of the body determined in the ambient magnetic field B is influenced by the shape and dimensions of the body. Thus the measured (apparent) magnetic susceptibility  $\kappa_A$  should be corrected for this shape effect in order to get the shape independent true susceptibility  $\kappa_T$ . The true susceptibility as a shape independent parameter can be used as a comparative parameter between meteorites and asteroids.

The relation between the true and apparent volume susceptibility is characterized by the equations (1, 2):

$$\kappa_T = \frac{\kappa_A}{1 - N\kappa_A} \tag{1}$$

$$\kappa_A = \frac{\kappa_T}{1 + N\kappa_T} \tag{2}$$

where N is the demagnetizing factor. The demagnetizing factor is depending on the shape of the object and direction along which the magnetic susceptibility is determined. For ellipsoid-shaped bodies the demagnetization factor can be calculated along the ellipsoid axes using the approach of Osborn, 1945.

In table 2 the shape effect has been determined for the rotational ellipsoids with various a to b,c axis ratios and for the susceptibilities ranging from 500 to 500000  $10^{-8}$  m<sup>3</sup>/kg (0,016 to 16 SI, assuming density of 3200 kg/m<sup>3</sup>). It is apparent that at the susceptibility values ~0,1 SI the difference between  $\kappa_A$  and  $\kappa_T$  for elongated objects can reach more than 10 %. At even higher susceptibility values this difference is more pronounced and for values  $\kappa_T >> 1$  SI the equation (2) reach the form (3)

$$\kappa_A \approx \frac{1}{N}$$
(3)

This condition is met for iron and stony-iron meteorites and thus the apparent susceptibility  $\kappa_A$  is strongly controlled by the shape of the body and the true susceptibility value  $\kappa_T$  contains large uncertainty resulting in large scatter of the true susceptibility values (see figure 1).

All the meteorite susceptibility values presented in the figures 1 and 2 are corrected for the shape of the sample.

# **Determination of asteroidal magnetic susceptibility**

Knowledge of asteroidal magnetic susceptibility could help to identify the metallic nature of the asteroid interior without direct access. However, the determination of this parameter is not easy task. Magnetic susceptibility of the asteroid may be detected in three ways with various levels of uncertainty:

- 1. Passively from an induced magnetization by interplanetary magnetic field (IMF).
- 2. Actively using a surface probe (AC coil) attached to a lander.
- 3. Directly on a sample return from asteroid.
- 1. Remote determination of the asteroidal magnetic susceptibility from induced magnetization by interplanetary magnetic field

The interplanetary magnetic field (IMF) is carried through Solar System in the solar wind. When encountering the asteroid the IMF gets disturbed. The level of this interaction depends on the magnetic properties of the asteroid. The asteroids with low remanent magnetization and low magnetic susceptibility will cause minor distortion while the asteroids with high remanent magnetization and / or high magnetic susceptibility can cause high disturbances in the IMF.

Those interactions can be measured using an orbiting spacecraft equipped with a magnetometer. In the case of significant interactions between asteroid and IMF have been detected first task is to separate the interactions due to the remanent magnetization from those due to the induced effect. Only the induced magnetization contains the information about the magnetic susceptibility. The basic criteria used to separate the remanent and induced magnetization are the facts that remanent magnetization of an asteroid has a stable value and direction and thus rotates with the asteroid while the induced (by the IMF) magnetization has always the direction of the IMF and its magnitude correlates positively with the magnitude of the IMF (and with the magnetic susceptibility of the asteroid). The remanent magnetization of an asteroid can be also easily determined in the periods of low IMF magnitudes when the induced effects are negligible.

Once the remanent magnetic field of an asteroid is well determined or is proved that the asteroid has negligible remanence the induced magnetic field during the periods of the high IMF magnitudes can be used to determine the magnetic susceptibility (unpublished data, Kletetschka *et al.*, 2007).

The separation of the induced magnetic measurements according to the dipole rules will generate data sets containing induced magnetization that allow an estimate of magnetic susceptibility. However, the solar wind interaction with the surface is a complex process and has to be considered during such estimate of magnetic susceptibility (Omidi et al., 2002). In the case the plasma carrying the external magnetic field H is homogenous during the measurement period (couple of orbits), the resulting magnetic induction B measured on orbit of the asteroid is:

$$B = \mu H$$

$$B = \mu_0 \mu_r H$$

$$B = \mu_0 (1 + \kappa) H$$

$$B = \mu_0 H + \mu_0 \kappa H$$

$$B = \mu_0 (H + M)$$

$$B = B_s + B_a$$

$$(4)$$

where  $\mu$  is permeability,  $\mu_0$  is permeability of vacuum,  $\mu_r$  is relative permeability,  $\kappa$  is volume normalized magnetic susceptibility, M is magnetization induced by H,  $B_s$  is an induction from the Sun and  $B_a$  is an induction from the asteroid.

 $B_a$  propagates as magnetic dipolar field according to:

$$B_a = \frac{\mu_0}{4\pi} \frac{m}{r^3} \sqrt{1 + 3\sin^2 \alpha} \,, \tag{5}$$

where m is a magnetic moment of the asteroid, r is a distance form the center of the asteroid, and  $\alpha$  is the magnetic latitude of the dipole.

Dipole equation (5) can be detected as the difference between the asteroid induction  $B_a(90^\circ) = \frac{\mu_0}{2\pi} \frac{m}{r^3}$  over the magnetic pole (Case A in Figure 3) and asteroid induction  $B_a(0^\circ) = -\frac{\mu_0}{4\pi} \frac{m}{r^3}$  over the magnetic equator (Case B in Figure 3, note the negative sign reflecting the opposing direction in respect to inducing field

This difference due to dipolar character of the induced field suggests a scheme for detection of an induced component on board of the spacecraft. The data has to be transformed into a coordinate system such that the vertical direction is parallel to spacecraft-asteroid direction. If the magnetic field  $B_A$  is parallel to spacecraft-asteroid direction, we have the case A in Figure 3. If the magnetic field  $B_B$  is perpendicular, we have the case B in Figure 3. The difference between these two cases  $\delta B$  can be expressed as following:

$$\delta B = B_{A} - B_{B}$$

$$\delta B = B_{s} + B_{a}(90^{\circ}) - B_{s} - B_{a}(0^{\circ})$$

$$\delta B = B_{a}(90^{\circ}) - B_{a}(0^{\circ})$$

$$\delta B = \frac{\mu_{0}}{2\pi} \frac{m}{r^{3}} + \frac{\mu_{0}}{4\pi} \frac{m}{r^{3}}$$

$$\delta B = \frac{3\mu_{0}}{4\pi} \frac{m}{r^{3}}$$
(6)

where *m* is the magnetic moment for which we have:

 $B_{\mathfrak{s}}$ ).

$$m = MV_a$$

$$m = \kappa H V_a$$
(7)

where M is asteroid's magnetization,  $\kappa$  is bulk susceptibility (asteroid volume ( $V_a$ ) normalized) and H is magnetic field, so we have:

$$\delta B = \frac{3\mu_0}{4\pi} \frac{\kappa H}{r^3} V_a$$

$$\delta B = \frac{3}{4\pi r^3} \kappa V_a B_s$$
(8)

where  $B_s$  is the solar induction. Equation (8) allows detection of susceptibility of the entire asteroid from any data set satisfying the case A and B (Figure 3). For  $B_s$  we can use an average from values  $B_A$  and  $B_B$ :

$$B_{av} = \frac{B_A + B_B}{2}$$

$$B_{av} = B_s + \frac{B_a(90^\circ) + B_a(0^\circ)}{2}$$

$$B_{av} = B_s + \frac{\mu_0}{4\pi} \frac{m}{r^3}$$

$$B_{av} = B_s + \frac{\mu_0 H}{4\pi r^3} \kappa V_a$$

$$B_{av} = B_s + \frac{B_s}{4\pi r^3} \kappa V_a$$

$$B_{av} = B_s \left(1 + \frac{\kappa V_a}{4\pi r^3}\right)$$

$$B_{av} \sim B_s$$

$$(9)$$

because the term  $\frac{\kappa V_a}{4\pi r^3} = \kappa \frac{V_a}{3V_r} < \kappa \frac{1}{100} <<1$  for  $r > 1.5 r_a$  (radius of an asteroid) and susceptibility  $\kappa$ 

even  $\leq 1$ .

Finally we obtain:

$$\kappa = \frac{8\pi r^3}{3V_a} \frac{\delta B}{(B_A + B_B)} \tag{10}$$

This formulation (10) can be used to estimate the apparent bulk susceptibility  $\kappa_{bulk}$  of an asteroid.

The advantage of this method is that the magnetic susceptibility of the whole asteroid is determined. This gives us the susceptibility value representative for the whole asteroidal volume and free of surface related space weathering affects. However, comparing to the surface or sample return measurements the sensitivity and precision of this method is low.

Usual IMF in the asteroid belt is about in the order of nT but can reach larger amplitudes during the periods of the high solar activity giving better signal to noise ratio. The induced magnetic field decays with power of three of the distance from the asteroid thus requiring close orbits.

The detection limit and desired magnetometer sensitivity depends on two main factors – the strength of the IMF field and the orbiting distance. In order to estimate the detection limit we will use in our calculation a spherical asteroid, radius of the orbit twice large than the radius of the asteroid  $r = 2r_a$  (in order to meet the condition in equation (9)) and IMF strength 10 nT. Then, by using the approximation from equation (9):

$$B_s \sim B_{av} = \frac{B_A + B_B}{2}$$

and

$$V_a = \frac{4}{3} \pi r_a^3$$

the equation 10 will transfer to

$$\kappa = \frac{r^3}{r_a^3} \frac{2\delta B}{B_s} = \frac{8r_a^3}{r_a^3} \frac{2\delta B}{B_s} = \frac{16\delta B}{B_s}$$
 (11)

For asteroid with CH, E or H composition equivalent ( $\kappa_{bulk} \sim 1$  SI) and IMF strength 10 nT the measured variation due to the induced effect will be  $\sim 0.6$  nT and for CR, H or Urelite composition equivalent ( $\kappa_{bulk} \sim 0.1$  SI) the measured variation due to the induced effect will be  $\sim 0.6$  nT.

Thus in the case of strongly magnetic stony asteroids or metallic objects the detection of magnetic susceptibility (and thus estimate of the iron content) is possible using currently available magnetometers with  $10^{-1}$  nT -  $10^{-2}$  nT resolution. In the case of stony asteroids with lower magnetic content development of more sensitive instrumentation or use of other method (as described further) is needed.

Other problem is related to the time variation of the IMF. This method assumes IMF to be constant through the measurement period. Thus the measurement must be performed during the relatively stable IMF periods or the second spacecraft far from an asteroid is required to monitor the variations of undisturbed IMF.

# 2. Active detection of asteroidal magnetic susceptibility using a surface probe (AC coil) attached to a lander

In the case asurface landing is the part of the asteroid space mission, a simple AC magnetic coil surface probe can be used for the magnetic susceptibility measurement. This concept is described in detail in Rochette *et al.*, 2004. The advantage of this method is that the signal of the material induced by the coil is much stronger comparing to the IMF interactions. The depth penetration of the coil signal depends on its diameter (roughly equal to the coil diameter) and usually the flat surface is required for best precision.

However, the effect of the space weathering on the magnetic properties of the asteroidal surface is not well known. In the case of a solid rocky surface of an asteroid the combination of the surface susceptibility probe with the device similar to RAT (Rock Abrasion Tool) used on Mars Exploration Rovers could provide the magnetic susceptibility of the unweathered asteroidal material. Other disadvantage is that the surface material of the asteroid can be modified or contaminated through collisional impact processes. Due to those reasons the magnetic susceptibility determined by the surface probe may not be representative for the whole asteroid.

# 3. Directly measurement of the asteroidal sample return

In the case the sample of the asteroid is delivered to the terrestrial laboratories the magnetic susceptibility can be measured using sensitive and well calibrated laboratory instrumentation. However, the expected sample size of the sample return for the ongoing (Hayabusa) or planned mission is typically very small (~mg) and may also be influenced by the effects described in the previous case. Thus, it may not be representative for the whole asteroid as well.

# Mass vs. bulk susceptibility

The bulk volume  $V_B$ , mass m, bulk density  $\rho_B$  and shape are among the primary asteroid parameters determined during the orbital phase of the asteroid remote sensing mission. Knowledge of both bulk volume and mass of the asteroid enables determination of both bulk (volume normalized) and mass normalized susceptibility of the asteroid. The relation between mass and bulk susceptibilities is expressed by equation (11):

$$\kappa_{mass} = \frac{\kappa_{bulk}}{\rho_{B}} \tag{11}$$

The bulk susceptibility is essential to calculate the shape correction of the measured (apparent) susceptibility using the demagnetizing factor and equation (1). However the bulk volume  $V_B$  of the asteroid may vary according to the porosity of the asteroid. An asteroid of the same mass and grain volume  $V_G$  (and thus same amount of magnetic compounds), but higher pore volume  $V_P$ , will have larger bulk volume  $V_B$  resulting in the lower bulk susceptibility. Thus bulk susceptibility is not suitable for the magnetic classification purposes.

However, the mass m and grain volume  $V_G$  remains the same and thus susceptibility normalized by mass or by grain volume will remain independent on the change in porosity. For this reason it is suitable to first perform the shape correction of the apparent bulk susceptibility and then normalize the true bulk susceptibility by mass or grain volume in order to minimize the porosity effect. Then the mass (or grain volume normalized) true susceptibility can be directly compared to those of meteorites.

## **Conclusions**

Determination of the asteroidal susceptibility is not a trivial task, but is possible. Each of three methods described has its own advantages and disadvantages. The induced effects due to the IMF interactions can provide the susceptibility representative for the whole asteroid. However the precision of this method is lower and thus is suitable for the high susceptible bodies only. The use of surface probe or the laboratory measurement of the sample return can provide more reliable values and can bring results also for

materials of lower susceptibility (e.g. achondrites). However, these methods bring the information from the asteroid surface only and thus does may not be representative for the whole asteroid.

Once magnetic susceptibility is successfully determined, the amount and nature of the magnetic minerals can be inferred. Based on the susceptibility, asteroids can be classified in similar way as meteorites are. We expect the distribution of magnetic susceptibility among various asteroid compositions to reflect the distribution of their meteorite equivalents. Similarly as for meteorites, the range of the susceptibilities of some asteroid classes may overlap. But additionally to reflectance spectroscopy and other chemical and mineralogical remote sensing methods, the magnetic classification may refine the match among meteorite equivalent candidates.

Thus we propose a stepwise concept of asteroid characterization and classification. First, the spectral class will be determined based on reflectance spectroscopy classification and the corresponding meteorite clan will be determined. In a second step, based on the asteroid magnetic susceptibility as well as on chemical and mineralogical information from the instruments on board of the space probe, the matching meteorite group will be distinguished. This multidisciplinary approach will help us to get the most precise link among asteroids and meteorites.

Once the meteorite equivalent will be distinguished, other physical parameters (bulk and grain density, porosity) of the asteroid and corresponding meteorite group in the database can be compared in order to determine more information about the internal structure asteroid. For example, by comparing the bulk and grain densities of the asteroids and meteorites, the amount of micro- and macro-porosity can be estimated. The micro-porosity is assumed to be similar among asteroids and related meteorites due to the small (sub-millimeter) pore size. This approach was applied in past studies to determine amount of the micro- and macro-porosity and the internal structure (rubble pile vs. onion skinned) of the asteroids Eros (Wilkinson *et al.*, 2000) and Itokawa (Abe *et al.*, 2006). The macro-porosity observed on asteroids is not preserved in meteorites because of the large-scale cracks / faults building the pore space. In this case the meteorites are simply too small to preserve those large scale cracks.

## Acknowledgments

### Figure and table captions

Table 1: New mass normalized (KM) as well as volume normalized (KV) shape corrected magnetic susceptibility values, bulk (BD) and grain (GD) densities and porosities (P) of meteorite samples obtained using the mobile laboratory.

Legend to the collections and meteorite classes:

EUB - Eötvös. University, Budapest, Hungary

GMO - Geological Museum, Oslo, Norway

HMNHB - Hungarian Museum of Natural History, Budapest, Hungary

GSHB - Geological Survey of Hungary, Budapest, Hungary

HUB – Humboldt University, Berlin, Germany

IGGL - Institute. of Geology and Geography of Lithuania, Vilnius, Lithuania

NHMS – Natural History Museum, Stockholm, Sweden

PO - Planetarium Olsztyn, Poland

TIGT - Tallinn Institute of Geology, Tallinn, Estonia

TUT – Tartu University, Tartu, Estonia

UM - Planetary Institute, University of Münster, Münster, Germany

VUV - Vilnius University, Vilnius, Lithuania

ACA - Acapulconite

**AEUC** - Eucrite

AHOW - Howardite

AUB - Aubrites

**AURE** - Urelites

CX – Carbonaceous chondrites

H, L, LL – Ordinary chondrites

MES – Mesosiderites

Table 2: The shape effect has been determined for the rotational ellipsoids with various a to b,c axis ratios and for the susceptibilities ranging from 500 to 500000  $10^{-8}$  m<sup>3</sup>/kg (0,016 to 16 SI, assuming density of 3200 kg/m<sup>3</sup>).

Figure 1: Magnetic susceptibility vs. bulk density of various meteorite clans. The lowest magnetic susceptibility values are characteristic to achondrites, followed by the chondrites, stony-irons and irons. The carbonaceous chondrite clan shows lowest bulk densities followed by other stony meteorites, stony-irons and iron meteorites. The grey symbols show older data obtained in laboratory while the colored symbols show new data measured directly in the museums using portable instruments. Only unweathered falls are displayed.

Figure 2: Magnetic susceptibility vs. bulk density of various ordinary chondrite groups and of enstatite chondrite clan. The magnetic susceptibility increases from LL chondrites to L, H and E chondrites. The grey symbols show older data obtained in laboratory while the colored symbols show new data measured directly in the museums using portable instruments. Only unweathered falls are displayed.

### Figure 3:

Green and blue circles indicate magnetic orientations of the vector magnetic data during the orbiting of the asteroid. Background image (Eros asteroid) is shown just for concept visualization. A: Magnetic field directions (green circles) is directed towards the asteroid at the magnetometer location. B: Blue circles indicate magnetic vector directions of the magnetic field pointing 90 degrees away from the asteroid direction.
