Phenomenological models for the antiferromagnetic vs. d-wave superconductivity competition in cuprates are studied [1] using conventional Monte Carlo techniques. The analysis suggests that cuprates may show a variety of different behaviors in the very underdoped regime: local coexistence, stripes, or, if disorder is present, states with Nanoscale superconducting clusters. The transition from an antiferromagnetic to a superconducting state does not seem universal. Under suitable conditions, non-superconducting Cu-oxides could rapidly [2] become superconducting by the influence of weak perturbations that align the randomly oriented phase of the superconducting clusters in the mixed state. Consequences of these ideas for angle resolved photoemission and scanning tunneling microscopy experiments [3] will also be discussed.
