# APPENDIX MODELING POPULATION TREND IN KITTLITZ'S MURRELET 

Chris Nations and Bryan Manly
Western EcoSystems Technology
Cheyenne, Wyoming
15 June 2002

## DATA

Data for these analyses were estimates of population size and their standard errors for the months of March (Table 1) and July (Table 2) in Prince William Sound, as well as estimates of population density and their standard errors in Glacier Bay (Table 3). Note that standard errors were obtained from the $95 \%$ confidence intervals provided to us using $\mathrm{SE}=\mathrm{Cl} / 1.96$.

## METHODS

In the main part of this report a model is proposed for determining population trends in Kittlitz's Murrelets (KIMU) and Marbled Murrelets (MAMU). This model accounts for the unidentified birds, and assumes that the probability of being identified is the same for both species but differs from year to year. The model also assumes that KIMU and MAMU have different but constant trends over time. Let $N_{K}$ and $N_{M}$ represent the unknown numbers or densities of KIMU and MAMU, respectively, in the starting year, $t_{0}$. The symbols $K_{t}, M_{t}$, and $U_{t}$ are the estimates of KIMU, MAMU, and unidentified birds, respectively, in year $t$. Let $\theta_{K}$ and $\theta_{M}$ represent the annual population trend for KIMU and MAMU, respectively, let $\gamma_{t}$ be the probability that a bird will be identified in year $t$, and let $E_{K t}, E_{M t}$, and $E_{U t}$ represent sampling error terms. The model is then

$$
\begin{aligned}
& K_{t}=N_{K} \theta_{K}^{t-t_{0}} \gamma_{t}+E_{K_{t}} \\
& M_{t}=N_{M} \theta_{M}^{t-t_{0}} \gamma_{t}+E_{M_{t}}
\end{aligned}
$$

and

$$
U_{t}=\left(N_{K} \theta_{K}^{t-t_{0}}+N_{M} \theta_{M}^{t-t_{0}}\right)\left(1-\gamma_{t}\right)+E_{U_{t}}
$$

We estimated the parameters in this model through a weighted least squares nonlinear regression. Let $t_{0}, \ldots t_{n}$ represent the years of available estimates, the unknown parameter vector be denoted by $\Theta=\left[N_{K}, N_{M}, \theta_{K}, \theta_{M}, \gamma_{t 0}, \ldots, \gamma_{t n}\right]$, the expected population size be represented by $f(\Theta)$, and let $Y_{t}$ and $V_{t}$ represent the population estimate and its variance, respectively, for all birds. Least squares regression seeks the best estimate of $\Theta$, denoted $\hat{\boldsymbol{\Theta}}$, such that

$$
Q=\sum_{t}\left\{\left[Y_{t}-f(\hat{\boldsymbol{\Theta}})\right] / V_{t}\right\}^{2}
$$

is minimized.

We obtained estimates of the variance of $\hat{\boldsymbol{\Theta}}$ via simulation. We assumed that population sizes or densities for all three groups of birds (KIMU, MAMU, and unidentified) were lognormally distributed with means and variances given by the estimates in Tables 1-3. Population sizes or densities were generated for each group of birds and then parameters were estimated using nonlinear regression. Empirical
variances were obtained from the set of all parameter estimates. Each simulation based on an original dataset entailed 5000 iterations, though the nonlinear optimization routine failed to converge occasionally, but always less than $3 \%$ of the iterations.

The data from Prince William Sound in March (Table 1) were problematic because of the presence of zero standard errors. In principle, estimated mean sizes of zero are not a problem, but as the formula for weighted regression shows above, the minimization criterion $Q$ is undefined for zero variance. Therefore, our analysis of the March data is based only on the years 1990, 1991, 1993, 1996, and 1998. A more complicated analysis might be possible (e.g., substitution of small non-zero values for the offending standard errors), but due to time constraints we chose the more straightforward approach. The consequence of excluding 4 of 9 years with very low estimates is likely an upward bias in the trend estimates.

We analyzed three subsets of the data from Prince William Sound in July (Table 2): (1) including all years; (2) excluding 1972; and, (3) excluding both 1972 and 1993. Note that the estimates for population size and its standard error for KIMU were both unusually large in 1972, while in 1993, the estimated number of unidentified birds was extremely large.

All analyses were conducted in Matlab 6.0.

## RESULTS

Parameter estimates for initial population sizes ( $N_{K}$ and $N_{M}$ ) were somewhat sensitive to initial guesses used in the nonlinear optimization. However, estimates for all other parameters were quite stable, irrespective of initial guesses. For results reported here, we used "reasonable" initial guesses based on available information. Initial values for $N_{K}$ and $N_{M}$ were taken from estimated sizes or densities in year $t_{0}$ (Tables 1-3). In all simulations, the other initial values were $\theta_{K}=\theta_{M}=1$, and $\gamma_{t}=\left(K_{t}+M_{t}\right) /\left(K_{t}+M_{t}+U_{t}\right)$. Initial values for $\theta_{K}$ and $\theta_{M}$ represent stable populations, and the initial values for $\gamma_{t}$ values are the observed proportions of identified birds. Means and standard deviations of parameter estimates from the simulations are shown in Tables 4-8.

The parameter estimates suggest that KIMU is declining ( $\theta<1.0$ ) in both seasons and in both locations. Furthermore, MAMU is declining in most cases; the exception is Prince William Sound in March (Table 4), where $\theta_{M}=1.1172$ (an increase of $11.72 \%$ per year). In general, the estimated rate of decline is much greater for KIMU than for MAMU except at Glacier Bay (Table 8) where the trends are very similar. Using all data from Prince William Sound in July (Table 5), the estimate of $\theta_{K}$ is 0.8186 (a decline of $18.14 \%$ per year). Excluding data from 1972 (Table 6) or both 1972 and 1993 (Table 7) results in even lower estimates of 0.6898 and 0.6844 , respectively (declines of $31.02 \%$ $31.56 \%$ per year). The estimates of $\theta_{M}$ and $\gamma_{t}$ (for those years in common) are strikingly similar in all three cases, though, of course, the estimates of both $N_{K}$ and $N_{M}$ differ substantially, depending on the starting year.

Table 4. Parameter estimates for the model of population trend for Prince William Sound in March. Means and standard deviations are from the simulation of lognormally distributed populations, based on 4892 iterations.

| Parameter | Mean | Standard Deviation |
| ---: | ---: | ---: |
| $N_{K}$ | 2254 | 1139 |
| $N_{M}$ | 15031 | 2682 |
| $\theta_{K}$ | 0.6857 | 0.0632 |

| $\gamma_{1990}$ | 0.5558 | 0.0340 |
| $\gamma_{1991}$ | 0.4161 | 0.0450 |
| $\gamma_{1993}$ | 0.1828 | 0.0312 |
| $\gamma_{1996}$ | 0.7663 | 0.0454 |
| $\gamma_{1998}$ | 0.9436 | 0.0175 |
| $\gamma_{2000}$ | 0.9799 | 0.0097 |

Table 7. Parameter estimates for the model of population trend for Prince William Sound in July, using data from 6 years (excluding 1972 and 1993). Means and standard deviations are from the simulation of lognormally distributed populations, based on 5000 iterations.

| Parameter | Mean | Standard Deviation |
| ---: | ---: | ---: |
| $N_{K}$ | 9080 | 2380 |
| $N_{M}$ | 93222 | 4922 |
| $\theta_{K}$ | 0.6844 | 0.0368 |
| $\theta_{M}$ | 0.9492 | 0.0090 |
| $\gamma_{1989}$ | 0.6083 | 0.0342 |
| $\gamma_{1990}$ | 0.5548 | 0.0348 |
| $\gamma_{1991}$ | 0.4225 | 0.0464 |
| $\gamma_{1996}$ | 0.7644 | 0.0437 |
| $\gamma_{1998}$ | 0.9433 | 0.0179 |
| $\gamma_{2000}$ | 0.9794 | 0.0099 |

Table 8. Parameter estimates for the model of population trend for Glacier Bay. Means and standard deviations are from the simulation of lognormally distributed populations, based on 5000 iterations. $N_{K}$ and $N_{M}$ represent densities.

| Parameter | Mean | Standard Deviation |
| ---: | ---: | ---: |
| $N_{K}$ | 7.76 | 1.57 |
| $N_{M}$ | 49.26 | 5.22 |
| $\theta_{K}$ | 0.8334 | 0.0312 |
| $\theta_{M}$ | 0.8298 | 0.0134 |
| $\gamma_{1991}$ | 0.6469 | 0.0465 |
| $\gamma_{1999}$ | 0.6438 | 0.0688 |
| $\gamma_{2000}$ | 0.4650 | 0.0483 |

Figure 1 shows the estimated and predicted population sizes for all three groups of birds for Prince William Sound in March. Particularly for KIMU, the model appears to fit the estimates reasonably well. Similarly, Figure 2 shows population sizes for Prince William Sound in July, using data for all years. Predicted population sizes for KIMU change when questionable data are excluded (compare Figure 2a to Figures 3 and 4). Omitting the problematic years leads to smaller residuals (estimated-predicted) in 1989 and 1990, but a larger residual in 2000. However, whether only 1972 or both 1972 and 1993 are excluded makes little difference in predicted population size for the years in common (compare Figure 3 to Figure 4). In general, the Figures 2-4 demonstrate that the model provides a reasonable fit to the population estimates. Though only three years of data were available for Glacier Bay, the model appears to provide a good fit to the data (Figure 5).

Considering the results for for Prince William Sound in July and assuming an initial (1972) population of 79179 as estimated in Table 5 , the estimate of $\theta_{K}$ leads to a predicted population of 291 in 2000, and the predicted population in 2025 is less than 2. On the other hand, starting with the 1989 estimate of 9080 and $\theta_{K}=0.6844$ (Table 7) yields a predicted population of only 140 in 2000. By 2012 the predicted population is less than 2. Of course, any prediction of extinction or quasi-extinction must be qualified by the unrealistic assumption of a constant rate of change in population size, and by the uncertainty in the population estimates.

In Glacier Bay the estimate of $\theta_{K}$ is 0.8334 . In this case the original estimates are densities (birds per $\mathrm{km}^{2}$ ) rather than population sizes. However, the implication of the estimated trend can be assessed by the fact that it implies that the population density in 2026 is predicted to be less than $1 \%$ of the density in 2000, and less than $0.1 \%$ of the 2000 density by the year 2039.
