## FY2004 Report:

Blood cell and plasma chemistry profile of adult Snortnose Sucker (Chasmistes brevirostris) during a blue-green algal bloom: USFWS - USGS cooperative live cage study in Upper Klamath Lake, July 2004.

J. Scott Foott<br>U.S. Fish \& Wildlife Service<br>California - Nevada Fish Health Center<br>24411 Coleman Hatchery Road<br>Anderson, CA 96007<br>(530 ) 365-4271, Scott_Foott@fws.gov<br>Fax 530-365-7150

Background- In support of the United States Geological Survey (USGS) monitoring program for both endangered suckers and water quality in Upper Klamath Lake, the California - Nevada Fish Health Center (FHC) conducted a cooperative study on physiological responses of adult suckers to extreme lake alkalinity ( $\mathrm{pH}>9.5$ ) during an algal bloom. Blue green algal (Aphanizomenon flos-aquae) blooms during the summer are often associated with high pH (>9.5), low dissolved oxygen levels (<2ppm after bloom crash), and elevated ammonia concentrations in the lake. These periods have been associated with fish kills in the recent past. This work was partially funded by the US Bureau of Reclamation (interagency agreement 04AA204033).

## Methods

In late June 2004, water quality monitoring by USGS determined that lake pH was markedly elevated in the northern portion of Upper Klamath Lake due to the initial algal bloom of the summer. Two sites with Hydrolab DataSondes ${ }^{\text {tm }}$ (GP5 and GP12) were selected for live cage deployment based on their initial difference in pH (Figure 1). Cages were held at the same depth and within 75 m of the dataSondes.

Adult Shortnose suckers (SNS), Chasmistes brevirostris, were captured alive by trammel nets. The nets were fished for 4 hours on the night of 29June near the Odessa creek region of Pelican Bay. Nets were examined at one hour intervals and captured fish were transported to the exposure sites and placed into live cages ( 1 m lengths of 0.5 m diameter PVC pipe enclosed with 5 mm mesh) suspended 1 m off the bottom by a float and anchor system. On 2 July and 8 July, fish were sampled at both sites and live specimens released back into the lake. Scales and otoliths were obtained from mortalities. An average time between live cage retrieval and blood collection was 5 minutes and ranged from 3-7 minutes. Fish were lightly anesthetized with MS-222, measured for fork length, the species and sex recorded, examined for external abnormalities (gill rot, hemorrhage, sores, copepod and leech infection), a $10 \mu \mathrm{~L}$ bacterial loop rubbed against the first gill filament and the mucus placed into a $40 \mu \mathrm{~L}$ pH 6.0 Phosphate buffer vial for lysozyme activity assay, a nonlethal gill lamellae clip (< 10 mg ) placed into a $100 \mu \mathrm{~L}$ of SEl buffer vial for gill ATPase assay, and a blood sample collected from the caudal vessels with a 1 cc heprinized syringe. The blood sample was processed immediately by removing $20 \mu \mathrm{~L}$ samples from the syringe with a sterile pipette to perform the following:

1. inoculate a slant tube of Brain Heart Infusion agar for bacterial isolation,
2. prepare a blood smear for differential leukocyte counts (absolute methanol fixed and later stained with a Diff-Quick ${ }^{\text {M }}$. kit),
3. load a microhematocrit tube for determining hematocrit (STATSPIN centrifuge)
4. load a $380 \mu \mathrm{~L}$ tube of Rees-Ecker fixative (20x dilution) for total white cell counts by hemocytometer,
5. hemoglobin assay (frozen on dry ice).

The remaining blood was centrifuged for $3-5$ minutes and 2 aliquots of plasma frozen on dry ice for clinical chemistry.

Blood cell assays: A differential leukocyte count was performed at 1000x magnification on the first 100 lymphocytes, thrombocytes, neutrophils, monocytes, and eosinophil / basophils observed on the smear. A Lymphocyte : Granulocyte ratio was calculated by dividing the number of lymphocytes observed by the sum of all neutrophils, eosinophils, and basophils. Total white cell counts (including thrombocytes) were performed with a hemocytometer on a 200X dilution of the sample. Rees-Ecker fixative contains Briliant cresyl blue dye and differentially stains leukocytes (Lucas and Jamroz 1961). Hemogloblin was assayed by a Raichem (San Diego, CA) kit using the Drabkin method.

Standard microscopic and biochemical tests (such as API-20E) were used to identify isolated bacterial colonies to the genus level.

Plasma chemistry: Plasma samples were stored at $-70^{\circ} \mathrm{C}$ until assayed for lysozyme activity, complement activity, cortisol, calcium, lipoperoxide, chloride, glucose, total protein, electrophoretic protein profile, albumin, and Albumin: Globulin ratio. Raichem kits were used for chloride, glucose, and albumin assays. Total protein concentration was determined by Sigma Chemical Company kit 541-2 and sodium was assayed with a flame photometer. Plasma protein electrophoresis was performed on $1 \mu \mathrm{~L}$ samples run on an agarose gel ( 1 M barbital buffer, 90 V for 35 min .). The amido black stained gels were scanned and the percent area of each fraction determined with Scanalytics Zero Dscan ${ }^{\mathrm{tm}}$ software. Four to five bands were observed on the gels with the farthest migrating band (anodic) defined as "albumin". Albumin is not found in all teleosts and its transport function can be performed by high density lipoprotein (Smet et al. 1998). No reference to sucker fishes and albumin were obtained in literature searches. The Albumin: Globulin (A/G) ratio was calculated from both the chemical tests for albumin and total protein (Albumin / [total protein - albumin = globulins]) as well as the electrophoretic profile (\% OD of $1^{\text {st }}$ band / [all other bands = globulins]). Low A/G ratios can indicate inflammation, kidney disfunction, and liver disease (Jacobs et al. 1990). Plasma lipid peroxide was assayed with a Kamiya Biochemical company kit (CC-004). Plasma cortisol concentration was assayed with an enzyme-linked immunoassay (Neogen, Lexington, KY) and a 3 order polynominal equation of the standard bound / unbound curve was used to derive the sample values. Plasma was diluted 100X in the kit's extraction buffer. The lysozyme activity of plasma and mucus (mOD $/ \mathrm{min} / \mathrm{mL}$ ) was determined from $20 \mu \mathrm{~L}$ samples assayed by a turbidimetric method at pH 6.4 (Ellis 1990). Hemolytic activity, of the alternative complement system, against rabbit erythrocytes was assayed by the method of Alcorn et al. (2002). Briefly, a $15 \mu \mathrm{~L}$ aliquot of plasma was diluted 15 X in buffer ( $0.1 \%$ gelatin, $0.1 \mathrm{M} \mathrm{EGTA}, 0.1 \mathrm{M} \mathrm{MgCl}$ in veronalbuffered saline), and reacted with $1 \%$ Rabbit red blood cells for 60 min at $15^{\circ} \mathrm{C}$. The hemoglobin content of the reaction well was determined by the absorbance at 540 nm . Percent hemolysis was calculated as follows: \{(Mean OD sample - Mean OD sample background) - (mean OD neg. control - mean OD Neg. control background) / (Mean OD $100 \%$ hemolysis control - mean OD hemolysis background)] * 100. Gill Adenosine Triphosphatase activity (ATPase $=\mu$ moles ADP $/ \mathrm{mg}$ protein $/ \mathrm{hr}$ ) was assayed by the method of McCormick and Bern (1989).

Blood values were compared with samples collected from presumptively healthy adult suckers in April 2003 and May 1997, as well as from suckers sampled in July and August 2003 during several algal bloom cycles (Appendix 1 and 2). These later 2003 samples also included 12 moribund fish (Foott 2004). Plasma chemistry values from carp, tilapia, and catfish were also compared due to the paucity of literature on sucker values (Appendix 3).

Figure 1. Map of exposure sites GP5 and GP12 in north Upper Klamath Lake. Data source http://or.water.usgs.gov/projs_dir/or207/klake_data_2003.html

## Results \& Discussion

Water quality- Mean daily water temperature between 28June and 8July ranged from 20.9 to $23.1^{\circ} \mathrm{C}$ at GP5 and from 20.3 to $24.9^{\circ} \mathrm{C}$ at GP12. There was a $2-3^{\circ} \mathrm{C}$ diurnal fluctuation at both sites (source http:// or.water.usgs.gov). Dissolved oxygen concentration remained above $6 \mathrm{mg} / \mathrm{L}$ at both sites during the exposure period. Peak daily DO values reached $12-15 \mathrm{mg} / \mathrm{L}$ with the percent saturation of oxygen well above $100 \%$ at both sites. Both daily mean and maximum percent oxygen saturation was greater at GP5 than GP12 with a peak of $213.5 \%$ on 1 July (Fig. 2). It is possible that these extremely high levels could induce gas bubble trauma or exert additional stress on the fish (Boyd et al. 1994. The influence of algal photosynthesis on water quality is apparent in the similar diurnal trends between pH and oxygen production (Fig. 3). Daily mean pH values ranged between 9.2 9.4 at GP12 while GP5 had mean values of between 9.5-9.8 (Fig. 3). Maximum pH measurements of 10.06 occurred at GP5 on 1July. While total ammonia (TAN) was not measured at either site, the alkaline nature of the water would result in between 55.7 $79.7 \%$ of the total ammonia being unionized (Emerson et al.1975). Bellerud and Saiki (1995) report that unionized ammonia concentrations of $>0.34 \mathrm{mg} / \mathrm{L}$ were toxic to SNS and Lost River sucker fry. Given the high percentage of NH3 at pH 9.8, a TAN of $0.6 \mathrm{mg} / \mathrm{L}$ would produce such toxic conditions. Suckers may employ compensatory mechanisms during ammonia stress. Lahontan cutthroat in pH 9.4 water compensate for ammonia excretion by the increase NH3 partial pressure in the plasma and were not depended on Na+ influx for excretion (McGeer et al. 1994).

A water sample collected at GP5 on 2July tested at $3.83 \mathrm{mg} / \mathrm{L}$ for total hardness (HACH kit and DR850 colorimeter, method 8030, $0-4.0 \mathrm{mg} / \mathrm{L}$ ). This value would appear low and is suspect. Bellerud and Saiki (1995) report that, during the spring, Upper Klamath Lake has a mean water hardness of $34.7 \pm 2.4 \mathrm{mg} / \mathrm{L}$ with a mean calcium hardness of $18.3 \pm 1.8 \mathrm{mg} /$ L. Wedemeyer (1996) states that waters with hardness less than $75 \mathrm{mg} / \mathrm{L} \mathrm{CaCO}_{3}$ are considered as soft waters and provide only limited buffering capacity.

Fish condition- A total of 20 SNS were placed into 10 live cages at each site on 29 June. At 60 hours post-exposure ("3 days") on 2July, one dead fish was encountered at GP12 with two GP12 cages lost when they broke loose from their buoys. One cage at GP5 was also lost due to vandalism or a break in a buoy line. At 216 hr ("9 days") post exposure on 8 July, there were 3 mortalities at both sites. A total of 10 fish ( $50 \%$ of test group) were lost from the study due to pre-sample mortality or loss of cage. The 4 female and 6 male SNS sampled alive were of a similar size range (Table 1). Live cage containment was the likely cause of the eroded fins, hemorrhagic skin around the snout, and some ulcers seen on the ventral and lateral body of the SNS (Table 1). Several ulcers were small and circular suggesting lamprey bites. No Lernea or columnaris (Flavobacterium columnare) lesions were observed on any of the SNS.

Blood cell and bloodborne bacteria - Total erythrocyte concentration, estimated by hematocrit values, were highly variable in the sampled SNS and ranged from 24 - 64\% (Table 2). This measurement is affected by sampling stress responses such as splenic contraction, erythrocyte swelling due to hypoxia, or plasma / tissue fluid shift (Houston 1997). Previous sampling of presumptively healthy Upper Klamath Lake adult suckers in the spring of 2003 and juveniles in 1997 had shown a similar range of hematocrit values (Appendix 1 and 2). Hemoglobin concentration showed a positive relationship to hematocrit with the mean corpuscular hemogloblin concentration (average MCHC $=24.1$ ) similar among the fish. These two measurements along with normal erythrocyte morphological seen in the blood smears indicate a normal erythrocyte profile.

NG no growth on media
The adult suckers generally appeared to have elevated circulating leukocyte numbers as might be expected in the summer months. Leukocyte numbers ranged from $40-226 \times 10^{6}$ cells $/ \mathrm{mL}$ with similar mean and median values of 128 and $124 \times 10^{6}$ cells $/ \mathrm{mL}$, respectively. Three GP12 fish $(\# 5,6,7)$ had leukocyte counts lower than 1 standard deviation of the mean and 2 fish collected on 8July (\#8 and 10) had values in excess of 1 standard deviation. I have no other sucker data for comparison however sexually mature Chinook salmon can range from $4-43 \times 10^{6}$ cells $/ \mathrm{mL}$ (unpublished FHC data on captive Winter-run Chinook leukocyte counts, 2004). I suspect that the measurement is prone to a large degree of laboratory assay variability. Aeromonid bacteria were isolated from the blood of 6 fish (Table 2). The mesophilic motile aeromonad complex (Aeromonas Pseudomonas =AP) are common inhabitants of the gastrointestinal tract and skin of freshwater fish. In 2003, these bacteria were isolated in both apparently healthy and moribund adults (Foott 2004).

All fish showed a neutrophilia (elevated) profile in the blood smears with neutrophils comprising 20-57 \% of all leukocytes (Table 3). These values were similar to adults sampled in July and August 2003 (Appendix 1 and 2). The Lymphocyte- Granulocyte (LG) ratios were $<2$ and well below the median 22 recorded in presumptively healthy adults sampled in April 2003. Such a shift can indicate infection, tissue damage, or seasonal blood cell changes (Modra et al 1998). Taken together, these leukocyte data indicate the live cage fish had been stimulated to increase blood cell phagocytic function in response to all or some of the following events: handling and captivity stress, summer water temperatures, or microorganism challenge. Gill sodium-potassium-Adenosine Triphosphotase activities ranged from $0.97-2.03 \mu$ mole ADP / mg protein / hr. These values have been observed in Chinook fry and may be relatively normal for freshwater fish (unpublished FHC ATPase calibration data).

Table 3. Differential leukocyte count and gill Na-K-Adenosine Triphosphotase activity. Leukocyte data recorded as percent lymphocyte (L), thrombocyte (T), neutrophil (N), monocyte or eosinophil (ME), and lymphocyte / granulocyte (+monocyte) ratio (L / G). ATPase activity is recorded as $\mu$ mole ADP / mg protein / hr.

Plasma samples - All fish showed highly elevated plasma sodium levels that were 59 135 \% above the normal freshwater fish value of 165 (Appendix 3). These sodium values were also above the mean $126 \mathrm{mmol} / \mathrm{L}$ value of the April 2003 adult suckers as well as the May 1997 samples (Appendix 1 and 2). The 1997 and 2003 values were likely lower than normal baseline values due to a capture stress response. Plasma chloride values were 25 $-60 \%$ below normal (freshwater fish normal minimum $\sim 100 \mathrm{mEq} / \mathrm{L}$, Appendix 3 ) in 8 of the 10 suckers. The 3 suckers sampled on 8July had significantly higher chloride values than the 2July group (t-test, 8df, $\mathrm{P}=0.027$ ). Exposure site did not affect chloride values in the 2July sample (t-test, $5 \mathrm{df}, \mathrm{P}=0.653$ ). The live cage fish values were similar to suckers sampled during the algal bloom of 2003 (mean ranging from $45-71 \mathrm{mEq} / \mathrm{L}$ ) but lower than the presumptively healthy adults sampled in May 1997 (Appendix 1 and 2).

Calcium concentrations ranged from $7-15 \mathrm{mg} / \mathrm{dL}$ and were within normal ranges for freshwater fish (Appendix 3). No site or date trend was detected by t-test statistical tests ( $\mathrm{P}<0.05$ ). Chronic stress was evident in the high plasma glucose and cortisol values seen in 9 of 10 suckers (Table 4). Triglyceride averaged $54 \mathrm{mg} / \mathrm{dL}$ and was similar among all 10 fish. The range of triglyceride values was similar to those observed in suckers sampled in May1997 (Appendix 1). Lipid peroxide (LPO) values were highly variable among the live cage fish and could have been influenced by the 5 week sample storage time (LPO assay
kit instructions state that 2 week storage was maximum for plasma samples). Three suckers (\#3, 7, and 9) had values $2-10 \mathrm{X}$ higher than the other fish and could have been experiencing oxidative stress. (Table 4). Palace et al. (1998) reported that adult lake trout livers had LPO values below $25 \mathrm{nmol} / \mathrm{g}$ and the LPO assay manufacturer states that human plasma should range from $0-1.3 \mathrm{ng} / \mathrm{mL}$. Lipid peroxides are produced by autooxidation of unsaturated fatty acids and are quite unstable in plasma.

Table 4. Plasma chemistry values for adult SNS exposed at GP5 and GP12 sites. Data reported for sodium ( $\mathrm{Na}, \mathrm{mEq} / \mathrm{L}$ ), chloride (Cl, mEq/L), calcium (Ca, mg/dL), glucose (Glu, $\mathrm{mg} / \mathrm{dL}$ ), triglyceride (TG, mg/dL), lipid perioxide (LPO, nmol/L), and cortisol ( $\mathrm{ng} / \mathrm{mL}$ ).

Water quality did not appear to have an obvious effect on plasma lysozyme levels. Plasma lysozyme activity ranged from $89-760 \mathrm{mOD} / \mathrm{min} / \mathrm{mL}$ while gill mucus yielded much more variable results (Table 5). The lack of correlation between plasma and mucus activity may be related to the influence of contaminating water on gill mucus collection. Despite the 8.5X difference in the minimum and maximum value, no obvious site or date trend was observed in the data. Plasma samples from suckers collected in late July 2003 had activities that ranged from $3800-33,000 \mathrm{mOD} / \mathrm{min} / \mathrm{mL}$ (unpublished data due to the large number of samples with no measurable activities). Some of these 2003 fish were moribund and had Columnaris lesions. Healthy juvenile Chinook salmon have been shown to have $2-4 x$ higher plasma lysozyme activities (Foott et al. 2004). Lysozyme is an important component of the innate immunity of fish with its ability to cleave bacterial cell wall peptidoglycan. It is produced by both macrophages and neutrophils in fish, and increased serum activity has been associated with activation of these phagocytes by infection (Paulsen et al. 2003). Schrock et al. (2001) reported detecting lysozyme activity in skin mucus of juvenile salmonids. Their activity data was 10 -fold less than that reported for salmonid kidneys containing phagocytic cells (Lie et al. 1989). Adverse water quality or severe handling stress is reported to induce a reduction in plasma lysozyme activity in trout (Mock and Peters 1990). Alternative complement activity (expressed as \% hemolysis of rabbit erythrocytes or AC50) was high in 9 of 10 fish (Table 5). No site or date trend was obvious in the data. The ACH50 value is calculated as the quality of plasma which will lyse $50 \%$ of standardized erythrocyte suspension (Yano 1992).

Table 5. Plasma enzyme activities for adult SNS exposed at GP5 and GP12 sites. Data reported for complement activity measurements: percent hemolysis of rabbit erythrocyte of a $10 x$ and 20x dilution as well as the alternative complement activity $50 \%$ level calculation, plasma ( $\mathrm{Pl} \operatorname{lyz}$ ) and gill mucus (Mu lyz) lysozyme activity ( $\mathrm{mOD} / \mathrm{min} / \mathrm{mL}$ )

nt $=$ not detected
Plasma protein values were elevated above presumptively healthy adults sampled in May 1997 (Appendix 1). If $3.0 \mathrm{~g} / \mathrm{dL}$ is set as a normal baseline (Appendix 1 and 3 ), the live cage suckers had protein values $1.3-2.6 \mathrm{X}$ above this value (Table 6). Elevated plasma protein and sodium levels all indicate hemoconcentration with a fluid shift out of the blood. Presumptive albumin was measured by both the Bromcresol Green assay (BCG) and from electrophoretic gels. Bromocresol green can bind alpha proteins as well as albumin and tends to over estimate albumin concentration in humans (Jacobs et al. 1990). Smet et al. (1998) reports that carp do not have albumin per se but use High Density Lipoprotein (HDL) for albumin's transport functions. They report the HDL was the most anodic protein in electrophoresis gels. The A/G ratio ranged from 0.29 to 0.60 by chemical methods and 0.30 to 0.45 by electrophoresis. These A/G values are lower than those observed in presumptively healthy suckers examined in May1997 or April 2003 (Appendix 1 and 2). They are similar to ratios seen in the July 2003 suckers collected during algal bloom cycles and may represent the "normal" elevation in globular proteins that occur in the summer months. Low Albumin : Globulin ratio is an indicator of liver dysfunction and infections in other vertebrates. Given the uncertainty about the presence of albumin in SNS, this immune function parameter may not be useful for critical evaluations.

Table 6. Plasma proteins.

Plasma sodium and protein disturbance factors - During stress events, most freshwater fish tend to lose monovalent ions by branchial efflux. This ion efflux occurs due to a combination of increased blood pressure and lamellar perfusion. Divalent ions in the water, such as calcium, reduce this branchial efflux by decreasing gill permeability. The sodium loss in stressed fish rearing in soft-water is magnitudes greater than in hard water. Fish recover their NaCl balance through branchial transport mechanisms (McDonald and Milligan 1997). Acute exposure to alkaline water ( $\mathrm{pH}>9.5$ ) is reported to inhibit both ammonia excretion and $\mathrm{Na}+$ influx in rainbow trout (Wright and Wood, 1985). Unlike the hypernatremia (high sodium) observed in the live cage fish, the previous examples result in reduced plasma sodium concentrations. Sodium and chloride movements are reportedly linked to acid- base regulation due to $\mathrm{Na}+$ / $\mathrm{H}+$ and $\mathrm{Cl} / \mathrm{HCO} 3$ - exchange processes (Wilkie and Wood 1996). The elevated sodium levels measured in the live cage suckers would also suggest a disruption of the fish's acid-base regulation. The mechanism(s) to explain the hemoconcentration trend is unclear and may require consultation with experts in alkaline water and stress fish physiology as well as further experimentation. If confinement stress played a role in this fluid shift, it could confound interpretation of alkalinity effects.

Summary:

1) All fish may have experienced a fluid shift from their circulation (as showed by high plasma protein and sodium values). The imbalance would likely impair acid-base balance and gas transport mechanisms.
2) The oxygen supersaturation experienced by the fish could induce gas bubble trauma. Total gas saturation would need to be measured before concluding any risk.
3) Confinement and handling stress responses were demonstrated in the elevated plasma cortisol and glucose values. Chronic stress could confound interpretation of alkalinity effects.
4) Immunosuppression was not apparent in the fish (plasma lysozyme and complement activities, AG ratio, leukocyte profile showing neutrophilia, and total WBC counts indicate a heighten level).

Acknowledgements: USGS-BRD Biologists with the Klamath Falls field station captured fish and assisted with sampling. In particular I thank Scott Vanderkooi, Brian Hayes, and Mark Johnson for their help. Water quality data was obtained from the USGS website (http://or.water.usgs.gov). Rick Harmon, Ken Nichols, and Ron Stone with the CA-NV FHC were involved with different aspects of the collection and laboratory analysis.
