Quarterly Status Report #1

"Investigation of New Systems for Potential Laser Action"

Grant NGR 22-011-025

Period Covered: 1 December 1968 through 28 February 1969

Date Submitted: 4 April 1969

Sponsored by the

National Aeronautics and Space Administration

Electronics Research Center

submitted for the staff by

John L. Roebber

I. Purpose of This Research

The purpose of this research is to find new chemical systems which can exhibit laser action. Metal compounds which can undergo photodissociation have been selected as the most promising candidates for laser applications. The project involves the spectroscopic study of selected metal derivatives, the characterization of any chemical changes which occur on their photolysis, and the performance of cavity experiments for the detection of laser action.

II. Research Activities Undertaken and Planned

During this quarterly period, we have been engaged in studies of the emission spectrum of HgI in the near infrared and vacuum ultraviolet regions excited by a microwave discharge, of the fluorescence spectra of HgI₂ and its fragments in the visible and near infrared and of the electronic absorption spectra of the mercury halides.

A. Microwave Excitation Experiments on HgI₂

Since most practical lasers have been those excited by electron impact, we have examined the emission when HgI₂ is subjected to a microwave discharge. Most of the effort has been devoted to the region from 2000 Å to 1600 Å using a one meter vacuum ultraviolet monochromator equipped with a photoelectric detection system. A 50 micron slit width was used, resulting in a measured instrumental band width of 1.0 Å. Numerous molecular bands and atomic lines were found. As expected, the atomic lines could all be identified with well known lines of iodine or mercury.

The intensity of the molecular bands is a strong function of the pressure in the discharge tube. In all cases the molecular bands showed a distinct degradation of rotational band heads to the red and appeared to be arranged in simple vibrational progressions. In the 2170-2110 A region, these bands agree in position with the most prominent bands in the H system of HgI reported by Ramasastry and Rao.¹ Since the bands below 2110 A have the same general appearance as those between 2170 and 2110 A (i.e. sharp and degraded to the red), they are probably HgI bands.

Unfortunately, molecular iodine^{2,3,4} is reported to have many emission bands in this region and mercury^{3,4} has a few. Blank experiments were carried out in which I₂ and Hg were separately subjected to microwave discharges under experimental conditions as close as possible to those used for HgI₂. No molecular bands were found at the same places from Hg and I₂ as from HgI₂. However, the extreme sensitivity of the bands to experimental conditions prevent these blank experiments from being entirely conclusive. The I₂ bands are reported^{2,3,4} to be degraded to the blue instead of the red, which makes it seem very unlikely that I₂ can be responsible for the bands we observe.

During the next quarterly period, we plan to examine the spectra produced by microwave discharges through vapors of ZnI₂, CdI₂ and PbI₂ and related MX₂ metal halides. The reason for examining these compounds in the 1600-2000 A region is two-fold. First, the spectra of ZnI, CdI and PbI have not been

reported in this region. Since they are so closely related to HgI, their spectra should aid in the interpretation of the spectrum of HgI. Secondly, if the same bands should be obtained from any of these compounds as we have obtained from HgI₂, then we will know that the spectrum we have been observing is not that of HgI but some common product such as I₂ or Hg₂. On the other hand, failure to find the same bands can be taken as pretty conclusive proof of the correctness of our identification of the spectrum as due to HgI since a wide variety of experimental conditions will have been employed in examining the spectra from the MX₂ compounds.

A preliminary survey of the emission spectrum from a microwave discharge through HgI₂ in the near infrared region from 1-2.7 microns was made using a Block Engineering Model 200S Interferometer Spectrometer equipped with a PbS detector. Numerous emission lines were found in this region, but because of the low resolution of this instrument (40 cm⁻¹ maximum) it was difficult to distinguish atomic lines from molecular bands. Furthermore, the PbS detector prevented examination of the 3.2 micron region where the $2_{\pi_{1/2}} \rightarrow 2_{\pi_{1/2}}$ transition of HgI is expected to occur. The Block instrument was used because it was being employed for the HgI₂ fluorescence experiments which will be discussed below, but it is not well suited for the microwave spectra. Next quarter, the near infrared spectrum will be examined using a grating instrument equipped with a detector sensitive to beyond 3.2 microns.

B. Gas Phase Fluorescence Spectra From HgI_2

Terenin and his group⁵ had reported that either

can occur, with high energy radiation favoring the former process. Here I^* was presumed to be the $^2\text{P}_{1/2}$ state of the iodine atom although there was no direct experimental evidence for this. The assignment was made solely by analogy with diatomic metal halides. If the $^2\text{P}_{1/2}$ state of the iodine atom is indeed produced as postulated by Terenin, then there should be no problem in achieving laser action at 1.315 microns due to the inversion of population between the $^2\text{P}_{1/2}$ and $^2\text{P}_{3/2}$ states of dissociated atomic iodine, as in the case of CF_3I .

During this quarter we first checked the result of Terenin that illumination of HgI_2 in its 2660 Å absorption band produces no fluorescence from HgI in the visible region. The fluorescence apparatus described in Progress Report #2 was used with the modification that the Jarrell-Ash 8200 scanning monochromator was replaced by a small Bausch and Lomb monochromator. We found no visible fluorescence in agreement with Terenin's results.

We next looked at the 1.3 micron region using a PbS cell hooked to a lock-in amplifier as our detection system. No fluorescence could be detected in the initial experiments. While efforts were underway to optimize the sensitivity of the apparatus, a Block Engineering Model 200S Interferometer

Spectrometer became available for use. Since this is an extremely sensitive instrument, we immediately substituted it as the analyzing unit. No iodine atom emission was obtained. However, these initial experiments were quite crude. Minor improvements in the arrangement of the apparatus using the Interferometer to better advantage should result in an increase in sensitivity of several orders of magnitude. During the next quarter, after these changes are made, the sensitivity of the whole apparatus will be calibrated. In addition, excitation of HgI_2 in its shorter wavelength bands will be tried and the near infrared emission spectra examined.

C. Gas Phase Absorption Spectra of HgI_2 and HgBr_2

Spectral studies of the metal halides were undertaken to aid in understanding their electronic structure and hence indirectly in evaluating their laser potential. The vacuum ultraviolet absorption spectrum of HgI_2 was reported in Progress Report #4, and that of HgBr_2 in Progress Report #5. The data obtained at that time were in the form of strip chart records of I_0 and I as a function of the counter reading of the monochromator.

Since that time, the relative light intensities I_0 and I have been read from the recorder charts at intervals of 0.2 - 0.3 Å using a digital curve reader and placed on punched cards. The absorption coefficient k , in cm^{-1} , was then calculated at each wavelength from the usual expression

$$k = \frac{1}{\ell} \frac{760}{P} \frac{T}{273} \ln \frac{I_0}{I}$$

Appropriate corrections were made in the calculation of k for the small scattered light level (less than 5%). Wavelengths were determined by fitting the locations of known emission lines to a straight line using the method of least squares. Wavelengths were converted into wavenumbers and the absorption coefficient k versus wavenumber was plotted automatically.

These computer plots of the HgI_2 and HgBr_2 spectra became available during this quarterly period and have been subjected to a preliminary analysis. Table I lists the oscillator strengths, f , and the positions of the band maxima for mercuric iodide and mercuric bromide. The oscillator strengths are only approximate because the mercuric halide pressures were assumed to be the equilibrium vapor pressure and it was difficult to be sure that the temperature measured was at the coldest region of the cell. The diffuse vibrational structure on the 2080 \AA band and the comparatively sharp structure on the 1800 \AA band of HgI_2 and the 1830 \AA band of HgBr_2 had been observed previously by Wieland.⁶ Wehrli⁷ has made a careful study of the structure on the 2080 \AA band of HgI_2 , the 1830 \AA band of HgBr_2 , and the 1690 \AA band of HgCl_2 . He has made an essentially complete vibrational analysis of all three bands. His band maxima and vibrational assignments for the 2080 \AA band of HgI_2 and the 1830 \AA band of HgBr_2 are shown in Tables II and III. Our results agree with those of Wehrli within the experimental error of locating the maxima of diffuse bands and our lower resolution.

Wieland⁶ reported structure on the 1800 Å band of HgI₂, which we also obtain (see Table II). Interestingly enough, Wehrli did not study this band, and no vibrational assignments have been made for it. Wieland⁶ found a very weak band at 1750 Å in the spectrum of HgBr₂, but attributed it to impurities. Our spectra of HgBr₂ show a band at 1750 Å which has diffuse vibrational structure on it (see Table III). Although it may not be obvious from Tables II and III, mercuric iodide's 1800 Å band and mercuric bromide's 1750 Å band both look very similar to the 1830 Å band of HgBr₂. No detailed analysis of these two bands has yet been attempted, but the same pattern found by Wehrli for the 1830 Å band of HgBr₂ does seem to fit them as well.

On the basis of Wehrli's vibrational analysis, Sponer and Teller⁸ have assigned the 1690 Å, 1830 Å, and 2080 Å absorption bands of HgCl₂, HgBr₂, and HgI₂ to $\Sigma_u^+ \leftarrow \Sigma_g^+$ transitions. If our preliminary vibrational assignments are correct, then the 1800 Å band of HgI₂ and the 1750 Å band of HgBr₂ can also be assigned to $\Sigma_u^+ \leftarrow \Sigma_g^+$ transitions. Such transitions are allowed in linear molecules, and it is somewhat surprising to find oscillator strengths as small as 0.003 for the 2080 Å band of HgI₂ and 0.001 for the 1750 Å band of HgBr₂. Even the oscillator strengths of 0.02 for the 1800 Å band of HgI₂ and 0.01 for the 1830 Å band of HgBr₂ are small for allowed transitions.

The very diffuse vibrational structure on the 2240 Å band of HgI_2 has not previously been reported in the literature. As Table II shows, this structure seems to consist mostly of a progression in 80 cm^{-1} . Since the ground state frequencies of HgI_2 are reported to be 156 cm^{-1} for the symmetric stretch, 33 cm^{-1} for the bending mode and 235 cm^{-1} for the asymmetric stretch,^{7,8} an 80 cm^{-1} vibration in an upper state is hard to understand. Any attempt to make a vibrational assignment must await a careful study of the effect of temperature on the intensities of these bands.
